NOTE.—The figures showing the yielding were taken from plotted results of the tests. The area of soil under load was approximately 3.6 sq. in. in all experiments, except that in No. 6 the area under load was 35.2 sq. in. In no case was the soil under load confined against lateral "flow."

The results stated below were derived on the basis of the further assumption that the original, as well as the strengthened, footings were "continuous;" in other words, that the footing for each buttress was 15 ft. wide. As a matter of fact, this assumption is hardly warranted, in so far as the original structure is concerned, as will be discussed in more detail later herein. Considering the loads to be carried by the buttress footings alone, the maximum soil pressures for the original structure would be approximately double those stated.

Referring to the typical sections of Plate XII, the computed pressures on the foundation soil, in the case of the original structure at Bay 35, are as follows:

I.—Under the "most severe conditions within the limits of reason", as set forth in Column (5), Table 3, with the exception that uplift pressure is considered to be negligible, the maximum vertical pressure on the foundation soil is 3 560 lb. per sq. ft.; the corresponding slant pressure is 6 000 lb. per sq. ft.

The foregoing assumptions, as also those in the three cases following, treat the horizontal thrust as taken up entirely by the frictional resistance of the foundation soil at the base of the footings. If the uplift pressure of Column (5), Table 3, were to be taken into account, the result would be to diminish the previously stated maximum soil pressures somewhat, but not to a considerable extent.

II.—If, for the sake of comparison, one similarly applies to Bay 35 of the original structure the more severe conditions which, according to Column (9), Table 3, are assumed to apply to the same section of the strengthened structure, the maximum vertical pressure on the foundation soil becomes 3 930 lb. per sq. ft.; and the corresponding slant pressure becomes 6 740 lb. per sq. ft.

The maximum soil pressures at the maximum height sections of the original structure are approximately the same as those indicated above for the typical section.

Due largely to the use of the new toe-wall (Plate XII), the unit compressive loads on the foundation soil were reduced considerably by the reconstruction, despite the fact that under the "most severe

conditions" the strengthened structure is considered to be subject to higher loading than the original structure. Thus:

III.—Under the "most severe conditions within reason", as set forth in Column (9), Table 3 (but disregarding any uplift pressure), the maximum vertical soil pressure for the strengthened structure at Bay 35 is 3 560 lb. per sq. ft.; the corresponding slant pressure is 4 795 lb. per sq. ft.

The latter pressure should be compared with that of 6 740 lb. per sq. ft. derived for the original structure under the same assumptions of loading (Case II). If, in Case III, uplift pressure had been assumed to be present, the results would not have been altered materially, because, in view of the assumed pivoting about the cut-off wall, uplift pressure under the "heel" would tend to increase the maximum compressive load on the foundation soil, whereas uplift pressure under the original footings down stream from the cut-off would tend to decrease such maximum load. Had the new "heel" been assumed to take up a portion of the horizontal thrust, the result would have been to increase the maximum vertical, but to decrease the maximum slant soil pressures.

IV.—Under the "normal maximum load" conditions of Column (7), Table 3, the maximum vertical soil pressure for the strengthened structure at Bay 35 is only 3 105 lb. per sq. ft.; and the corresponding slant pressure is only 3 550 lb. per sq. ft.

It is probable, therefore, that, in view of the strengthening of the original structure, the foundation soil under the higher portions of the structure will not be subjected to loads in excess of 4 000 lb. per sq. ft.

In the design of the footings of the new spillway section, between Buttresses 10 and 19, the fact that the footings rest directly on shale bed-rock made the problem comparatively simple, and detailed discussion appears to be unwarranted. In that section the maximum unit compressive load is approximately 5 tons per sq. ft., whereas, in the writer's opinion, the foundation shale can take at least 20 tons per sq. ft. in compression.

Strength of Footings.—Apparently, it was intended by the designers of the original structure that the load should be transmitted

into the foundation soil through the buttress footings only. Throughout the larger part of the structure the buttress footings are 7 ft. 6 in. wide. The intervening space, also 7 ft. 6 in. wide, between buttress footings, was apparently intended to be simply floored over with reinforced concrete, varying from 8 to 12 in. in thickness. Such flooring, however, was connected rigidly by reinforcing steel to the buttress footings, the heavier lower fiber reinforcement being cut at the center of each bay. In the study of the strength of these footings, in connection with the safe bearing value of the foundation soil, alternatives submitted themselves, neither of which afforded satisfactory results.

In the first place, if the buttress footings were considered to carry the entire vertical load, then manifestly the unit loads would be twice as great as those derived on the assumption that the footings are continuous across the entire 15-ft. width of the bays. For instance, referring again to the typical sections of Plate XII, such doubled maximum vertical soil pressure would become approximately 7 120 lb. per sq. ft., and the maximum slant pressure would become approximately 12 000 lb. per sq. ft. at the down-stream edge of the footings of the original structure under the "most severe conditions within the limits of reason". In the case of the strengthened typical section, such doubled maximum vertical and slant soil pressures would become approximately 6 090 and 8 190 lb. per sq. ft., respectively, under the "most severe conditions". The latter pressures, however, unlike those previously stated, are found at the up-stream edge of the original toe; for it is hardly conceivable that the new toe-wall, which is continuous for the sections of maximum height between old and new spillways, could act otherwise than as a continuous footing, in so far as the transmission of vertical load into the foundation soil is concerned.

The original footings, if assumed to extend only 3 ft. beyond each buttress, were approximately strong enough to carry the doubled unit loads just mentioned, but the adopted safe bearing value of the soil, *viz.*, approximately 5 000 lb. per sq. ft., would evidently be exceeded. Hence, it was imperative that the vertical load on the foundation soil should be distributed over a width of 15 ft., and not merely 7 ft. 6 in., for each buttress.

Turning then to the second or alternative assumption, it is readily seen that only by the use of continuous footings was it possible to keep the loads on the foundation soil within safe limits. As a matter of fact, even in the original structure, some load must necessarily have been carried by the intermediate flooring, inasmuch as it was strictly a part of the adjacent buttress footings. The main buttress footings could not take load (and hence deflect, by reason of compression of the underlying soil) without transmitting part of such load by shear into the adjacent flooring. It is probable, however, that in the downstream portions of the original footings such action caused stresses considerably in excess of the safe working stresses for concrete and steel.

Moreover, in the original portion of the structure, continuity of footings was necessary in order that the footings might act in harmony with the continuous horizontal, or upper, member of the new anchoring wall at the toe. The original footings, however, were not strong enough for this purpose. The weakness lay, not merely in the intermediate reinforced concrete flooring, but also in the main buttress footings themselves, for, under these conditions, the length of the cantilever (measured from the face of the buttress toward the center of the bay) becomes 6 ft. 9 in., instead of 3 ft., as under the former alternative assumption. Thus, in the case of the typical section (Plate XII) the allowable vertical soil pressure on the footings, with assumed working stresses of 700 lb. per sq. in. for the concrete and 18 000 lb. per sq. in. for the reinforcing steel, would be only about 1 700 lb. per sq. ft.

The adopted method of strengthening the footings is shown in the typical sections of Plate XII. It was accomplished by adding both concrete and reinforcing steel. The object was to enable the original intermediate flooring to act as a part of the main footings, which would thereby become continuous, and also to strengthen the original buttress footings. In view of the relatively short clear span of such continuous footings (about 13 ft. 6 in.), it appears reasonably certain that in transmitting the load into the foundation soil the footings act in part as inverted arches. It seemed proper to utilize such arch action in the design, and therefore the arbitrary, but not unreasonable, assumption was made that one-third of the load would be carried by the footings acting as arches and the remainder by the footings

acting as continuous slabs or beams. Such continuous beams have tension in the lower fibers at the buttresses, but have compression in the lower fibers at the centers of the bays.

Concrete was added on top of the original footings adjoining the bases of the buttresses, so as to make more effective the existing steel in the bottom of the footings; whereas, near the middle of the bays, the new concrete serves as a matrix for the new transverse reinforcing steel (bent as shown in section *A-A* of Plate XII). The new concrete was well tied and bound into the old concrete, both by steel dowels extending through the base of each buttress and into the original buttress footings, and also by the roughening of all surfaces of contact. This roughening was done partly with picks, by hand, but mainly by the use of air-hammers. After roughening, the surfaces were thoroughly cleaned and made wet before applying the cement grout coating which immediately preceded the placing of the new concrete.

The new footing concrete, however, has two other functions: First, it serves to embed the tie-steel leading down stream from the anchoring wall at the heel, and hence it was extended to the rear of the bays, even though there the original footings did not require reinforcement. Secondly, it serves to transmit the horizontal thrust from the buttresses and buttress footings into the tie-steel.

The approximately triangular section of concrete, shown in Section *B-B* of Plate XII, at the junction between deck and footings, has been referred to in connection with the description of the new anchoring wall at the heel, serving as it does to take up the reaction of the upper cantilever member of the "heel". The concrete of this triangular section was usually poured in connection with the new "heel", and prior to the placing of the new footing concrete.

At Bays 27 to 33, inclusive, extra depths of new concrete were added over the original footings. This was done partly in order to add strength by adding weight to these sections of maximum height. The quantities of concrete involved, however, were so great that, for the sake of economy, it was deemed advisable to leave a number of large pockets in the concrete. These pockets were made practically water-tight, and act as tanks. From the time that these pockets were first filled with water, they have remained full. Thus the only sacrifice in weight is that due to the difference between the specific gravity of water and concrete.

Another reason for adding such extra concrete was to raise the top of the strengthened footings at least 5 ft. above the bottom of the new outlet channel (shown by Fig. 17). The outlets from the sluice-gates in Bays 30 and 31 were covered with a substantial reinforced concrete slab which completely separates the gate openings and

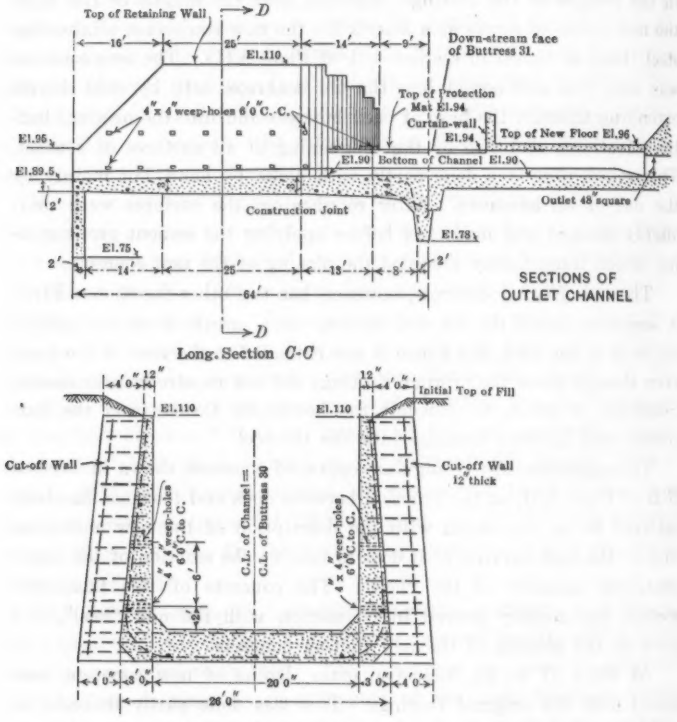

FIG. 24.

outlets from the operating mechanism. Consequently, no spray due to the opening of the gates can interfere with their operation, by freezing in winter, for instance. Moreover, it was thus possible to house in the operating mechanism of the gates entirely by carrying the slab (acting as a roof over the outlets) forward to meet the curtain-wall, as shown in the longitudinal sections of Fig. 24 and Plate XIII.

At the east end of the dam, beginning at Buttress 49, it was considered allowable, as already explained, to increase considerably the unit loads on the foundation soil. Hence, in that section, the original scheme was followed of utilizing the main buttress footings to carry the entire vertical load. For this purpose the original footing required only minor strengthening. Here the possible cracking of the intermediate flooring was considered to be of minor consequence; however, the tie-steel from the new "heel", extending as it does a comparatively short distance down stream from the "heel", was well covered with concrete, doweled both into the floor and the buttress footings.

Pressure Grouting Under Footings.—The contact between the original footings and the foundation soil was in some places found to be faulty. Generally, speaking, the original footings had not been carried into the foundation soil as deeply as might have been desired, in consequence of which certain soft spots required compacting. Also, hollow spaces were found under the footings around the 4 by 12-in. weep-holes which had been left at intervals in the footings as constructed originally. Such voids were probably due either to leakage from the reservoir or to flowing ground-water.

Moreover, it was discovered that, at least in some bays, the foundation soil had been washed away at the junction between the footings and the cut-off wall. This is shown clearly in Fig. 23 where the chalk line on the down-stream face of the original cut-off wall shows the extent of the erosion which had taken place. The photograph from which Fig. 23 has been reproduced was taken in Bay 19, but it was evident, from the conditions exposed during the wrecking of adjacent portions of the original structure, that the void in question had no connection with the break in the dam; instead, it probably communicated with a near-by weep-hole through the footings. It is believed, therefore, that this condition did not arise at the time of the failure, but had been brought about gradually by leakage through the unbonded construction joint at the top of the original cut-off wall. The construction joint would naturally open somewhat, due to the deflection of the foundation soil when loaded.

These faulty conditions, it was concluded, could best be remedied by pressure grouting. For this purpose, a Ransome-Caniff grout mixer, of about 4½ cu. ft. capacity, was used; air under pressure was obtained from a small compressing outfit, and utilized at pressures varying from

25 to 100 lb. per sq. in. at the grout mixer. The mixer, in turn, was connected to pipes sealed into the weep-holes with concrete or cement grout. Mixtures of cement and sand, in the proportions of 1:1 or 2:1, were used as far as possible, but, for the greater part of the work, neat cement grout was found to be more practical; the presence of sand in the grout was frequently the cause of clogging the pipe connections and consequent delay.

It was necessary to plug temporarily all weep-holes in the neighborhood of that to which grout was being applied under pressure. Observations showed that grout under pressure traveled under the footings for a distance of at least 100 ft. Inasmuch as the water contained in the cement grout helped to fill the voids, it was found necessary to adopt the process of forcing grout into the voids connecting with a given weep-hole until they refused to accept more, and then suspending grouting for a day or more. In the meantime the grout would set, leaving the uncombined water free to be blown from under the footings, on subsequent resumption of grouting, by simply unplugging temporarily a few communicating weep-holes. Such holes were then re-plugged and more grout was forced into the voids. This process was continued for each weep-hole until finally it was found that the hole would accept no more grout. After grouting had been completed and the grout had set, the weep-holes were again opened, so as to communicate with the underlying soil, by simply punching or drilling holes through the grout.

By these means, it is believed, the foundation soil under the original footings was thoroughly compacted so as to warrant the assumption that the footings are everywhere in contact with the foundation soil, either directly or through intermediate grout.

Leakage and Drainage.

Leakage Through Foundation Soil.—Reference has been made to the leakage which took place through the construction joint at the top of the original cut-off wall, and also to the fact that this trouble was remedied as an incidental result of the construction of the new anchoring wall at the heel. Further leakage, however, was discovered under and through the original cut-off wall, especially where the structure is of maximum height. During the work of investigation, prior to beginning actual reconstruction, test-pits were sunk up stream from,

and adjacent to, the original cut-off wall at Buttresses *B* and 37 (Plate IX). The pit at Buttress *B* was approximately 45 ft. deep, and by means of it the cut-off was investigated at its deepest section. In neither of these test pits was the cut-off wall found to be porous or the seal into bed-rock defective.

Except for a test pit sunk with great difficulty through the footings and foundation soil adjacent to the down-stream side of the cut-off wall at Bay 28, the investigation of the cut-off at the sections of maximum height was postponed until the actual work of reconstruction was being carried on. The cut-off in this region, *viz.*, between Buttresses 26 and 32, was relatively shallow, at least as compared with the hydrostatic head due to the reservoir; and therefore it was the more important that this portion of the cut-off should be impervious. The postponement of the investigation in this region was due only to the great expense of putting down test pits so near the river bed without adequate coffer-damming.

In connection with the excavation for the new "heel", therefore, test pits were sunk at intervals, and extending from the elevation of the bottom of the "heel" down to the bottom of the original cut-off. The findings in the test pit sunk through the footings in Bay 28 had already indicated, much to the writer's surprise, that the cut-off in that region was not all that it should be, and the test pits sunk from the trench excavation for the "heel" on the up-stream side of the cut-off confirmed these findings. It was definitely established that there was easy communication for water between the up-stream and down-stream sides of the cut-off wall at Bay 28. Probably some of the water which flowed back and forth, depending on the hydrostatic pressure conditions, passed through the cut-off wall itself; but, at this point, undoubtedly the greater part of the communication was underneath, through openings between the cut-off wall and the bed-rock.

At Bay 30, also, it was evident that the seal of the cut-off into bed-rock was imperfect. In fact, at one point a layer of sandy mud, averaging ¼ in. thick, was plainly visible between the concrete and the shale, indicating that, in the original construction, the trench had not been properly cleaned preparatory to the placing of concrete. Moreover, the cut-off wall itself was porous to the extent of allowing a constant trickle of water to pass through from the down-stream side. That there was any such leakage at all was the more noteworthy because

of the fact that the hydrostatic pressure on the down-stream side was due solely to the ground-water in the clayey foundation soil—though it should be remembered, of course, that the foundation soil under this maximum height portion of the dam is of poorer quality than that at any other part of the structure.

In view of the foregoing findings, it was determined to underpin the original cut-off wall for approximately 200 ft., *viz.*, from about Buttress 32 westward to the new spillway. A notch, about 24 in. deep and 18 in. wide, was cut into the bed-rock, with its center approximately at the up-stream edge of the original cut-off wall. The notch was carefully cleaned and kept free from water while it was being filled with a rich concrete which was carried to a height of at least 12 in. above the bottom of the old cut-off.

This work proved to be the most expensive part of the entire reconstruction, partly because of the constant fight with the water which flowed into the trenches through the pervious soil under the river-bed, and partly because of the fact that the character of the soil required practically continuous sheeting and bracing. So difficult, in fact, was it to carry on the work and to hold the up-stream side of the excavation for the "heel" that at Bays 30 and 31 it was found advisable first to pour the "heel" concrete and then, after that concrete had set, to tunnel under it in order to investigate the efficacy of the cut-off seal into the rock. Such tunneling was done from the adjacent bays, and, to insure solid work under the "heel" at Bays 30 and 31, grout pipes were inserted while the concrete for the cut-off underpinning was being placed, the ends of the pipes being exposed under these portions of the "heel". Later, the voids at the ends of these pipes were filled with grout, by using the Ransome-Caniff grout mixer, under a pressure of about 75 lb. per sq. in.

At certain places, as shown on Plate IX, the cut-off underpinning concrete was extended on the up-stream side of the cut-off up to the elevation of the bottom of the "heel". In such cases a slip joint was made between the "heel" and the underpinning concrete. This joint consisted essentially of a longitudinal groove, about 12 in. wide and 6 in. deep, lined with tar-paper. The groove was centered on the bottom of the "heel". When the "heel" concrete was poured, therefore, a tongue of concrete, likewise 12 in. wide and 6 in. deep, was formed in the groove integral with the "heel" concrete. On all horizontal

surfaces, and on the up-stream vertical face of the groove, single sheets of two-ply tar-paper were used to separate the two bodies of concrete. On the down-stream vertical face of the groove, however, three sheets of two-ply tar-paper were used.

The purpose of the slip joint is to allow the "heel" to move down stream a fraction of an inch under the horizontal thrust acting against the dam and hence transmitted by the tie-steel into the "heel". Without such "play" an unfavorable loading might be caused at the lower end of the long cantilever member of the "heel", because of the resistance of the relatively inelastic underpinning concrete. The latter, of course, is practically immovable because of its bond into the bed-rock. The utility of the slip joint is probably to be justified on theoretical rather than practical grounds, but, in view of the small expense involved, there seemed to be no warrant for omitting this precaution.

At about the middle of Bay 26 it was found that there was a pervious spot in the bed-rock strata just below the practicable limit of underpinning. Therefore a churn-drill hole was sunk into the strata in question, and grout pipe connections were made, which, after the completion of the underpinning and the new "heel", were utilized in an attempt to force grout into the stratum. However, a pressure of 75 lb. per sq. in. did not suffice to force down an appreciable quantity of grout.

It is not improbable that the failure to force more grout into this stratum was due to the fact that there was no vent for such rock-water as might have been displaced by grout had a means of escape for such water been provided. It happened that, for the grouting of the underpinning of Bays 30 and 31, as previously mentioned, two grout pipe connections had been left, and thereafter on the work, profiting by the experience at Bay 26, at least two grout pipes were placed in each void to be filled. Usually, the second pipe was connected to the pressure grouting apparatus only after the first pipe refused to accept any more grout. In such cases it was commonly impossible to force grout into the second pipe, and apparently the main function of that pipe was to serve as a vent. In the writer's opinion, it is not unlikely that some of the reported failures of pressure grouting operations at other dam sites have been due to the fact that no such vent existed, or had been provided, for the escape

of air or ground-water contained in the voids sought to be filled by grouting.

Referring again to the faults in the original cut-off construction, which required remedying by the means just described, the reconstruction afforded a rare opportunity for observing the results of this construction work, which had probably been done with average care. These observations show that great care is necessary even in foundation work, where it is too often assumed that any kind of work will suffice.

Extension of Cut-Off.—Inasmuch as the insufficient depth of cut-off wall in the neighborhood of the break in the dam was undoubtedly the direct cause of the failure, it was advisable to pay especially careful attention to any further deficiency in depth of cut-off. At the sections of maximum height, precautions were taken in the way of underpinning the original cut-off wall, as discussed previously. Such underpinning extended westward to the new spillway which in turn covered completely the area affected by the failure. (Plate XI.) Here the combination cut-off and anchoring wall at the heel extends into the shale rock to an average depth of about 10 ft., in the manner illustrated on Plate X. The depth is greatest in the neighborhood of Buttresses 14 and 15, because there, as mentioned previously, the rock was found to be somewhat shattered.

In the same region the rock yielded a considerable quantity of water, especially after the drain holes had been drilled. Consequently, after the combination cut-off and anchoring wall had been completed, a hole was drilled, with the Calyx machine, through a pipe which had been embedded in the center of the wall at about the middle of Bay 13. The hole penetrated the underlying shale to about Elevation 70. It was intended to grout this hole for the purpose of cutting off any communication with the reservoir which might exist in this neighborhood through passages in the rock under the cut-off. It was assumed that the existence of any such connection would be shown, when pressure grouting was applied, through the manifestation of bubbling or other symptoms at a drain hole extending to about the same elevation and approximately 7 ft. down stream in Bay 13. However, a surprise was afforded, in that the hole would accept no grout, and it was apparent that the rock-water passages, which had been tapped a short distance down stream in Bay 13, either came from a greater depth, or more

probably communicated to the westward—the slope of the bed-rock (Plate IX) being upward and westward.

West of the new spillway, beginning at Buttress 10, the depth of the original cut-off was as inadequate as at the point of failure. At some places, especially near steps in the bottom, the depth of the cut-off was less than 5 ft. below the bottom of the footings (Plate IX). It is probable that everywhere in this region, except possibly at one or two of such steps, the original cut-off extended to a depth of at least 6 ft. below the original ground surface. That the wall was not deep enough to cut off a pervious stratum of dark color in the overburden will be seen by referring to Fig. 7, in the upper right corner of which the bottom of the original cut-off wall is shown supported by a prop.

The entire west end of the dam, *viz.*, between Buttresses 1 and 10, was provided with a new "heel", the required depth of which varied from 1 to 5 ft. below the bottom of the original cut-off. The new "heel" was made not less than 2 ft. 6 in. wide at the bottom, this being a width convenient for trench excavation. A cut-off wall of this minimum width was then extended downward from the bottom of the "heel" to seal into the bed-rock. In this region the bed-rock consists of shale of a very good quality; in fact, in some places the rock is so hard that a notch only 6 in. deep was considered to afford a sufficiently good seal. At other places, however, the notching was carried to a depth of more than 3 ft. on account of penetrating a stratum of soft shale which in part overlies the very hard stratum.

At the bottom of the required depth of "heel" a standard slip joint was provided, in the manner previously described; and just under the old cut-off (but above the slip joint) a shoulder of concrete, with a minimum width of 12 in., was formed. The purpose of such a shoulder of concrete was to make certain that any vertical load transmitted into the old cut-off wall would in turn be taken up by the new "heel" and cut-off, thus guarding against any possible separation of the old concrete from the new and against the placing of any excessive shearing stress on the tie-steel connecting the new anchoring wall to the original structure.

As will be seen from Plate IX, a core-wall had been provided in the original construction extending 30 ft. west of Buttress 1. As a part of the reconstruction, this core-wall was extended upward to

the elevation of the new parapet (Elevation 142.5) and downward to seal into the shale. Also, because of the increase in assumed high water elevation, it was extended about 15 ft. farther westward. The precautions taken in providing a cut-off against percolation at the west end of the dam were of a more conservative nature, for the reason that it was near this end of the dam that the failure had occurred.

Between Buttresses 32 and 46 the depth of the original cut-off, with a maximum of 45 ft., was concluded to be sufficient in proportion to the maximum hydrostatic pressure. This conclusion was based on the fairly well substantiated assumption that in this region the original cut-off is impervious throughout its entire depth, but it did not depend on the character of the seal of the cut-off into the bed-rock. As a matter of fact, however, a personal inspection of the bond between concrete and rock as exposed by the test pits at Buttresses *B* and 37 convinced the writer that the seal is as effective as could be desired. East of Buttress 46, on the other hand, certain difficulties were encountered.

It had been assumed by the builders of the original structure that the cut-off extended to bed-rock at least as far east as the approximately vertical step in the cut-off at the middle of Bay 54 (Plate IX). In fact, all records of the original work show the cut-off as being in contact with bed-rock. It is not surprising, therefore, that the results of core-drill holes Nos. 3 and 8, sunk during the investigation prior to reconstruction, were discredited when they indicated that bed-rock was reached only at a considerable distance below the bottom of the original cut-off. Nevertheless, some mental reservations were made, and subsequently a test pit was sunk at the middle of Bay 48. The findings were by no means comforting, for, after penetrating flat-top boulders, the upper surfaces of which offered some reason for their previously erroneous identification as bed-rock, the pit extended through clay deposits into strata of disintegrated coal. Rock was not reached until at about Elevation 92. It is a shale, and quite satisfactory.

In view of the discovery of the disintegrated coal, which was decidedly pervious, the existing cut-off was manifestly inadequate. This was especially true of the portion east of the middle of Bay 48. It was concluded, therefore, to underpin the original cut-off down to a line sloping with approximate uniformity from Elevation 92 at Buttress 46 to Elevation 108 at Buttress 53, and meeting the bottom of the original

cut-off at the latter point. The proviso was made, however, that the disintegrated coal should be cut off wherever its top came within 1 ft. below the bottom of such sloping line. The probable genesis of the disintegrated coal and the measures taken to cut it off are shown on Plate IX. Drill holes Nos. 9 and 10 were sunk after the discovery of the disturbing conditions just described.

It was also concluded to underpin the original cut-off east of the middle of Bay 54, as well as the core-wall which originally extended 50 ft. east of Buttress 56. Excavation for the underpinning in these two localities proved to be very difficult because of the existence of a sandstone talus in the form of huge boulders. The most economical method was found to be the sinking of shafts from the surface of the ground and the construction of tunnel drifts leading from such shafts under the original cut-off. Some of the crevices discovered between the boulders were found to be filled with clay, and others were open. In one instance a crevice at least 2 in. wide was traced for 6 ft., and it extended even beyond that distance. The shattered rock was very difficult to excavate, and required frequent blasting.

Before the excavation was filled with concrete, grout holes were churn-drilled into the rock, and grout pipes were placed in crevices so that later, when these were pressure-grouted, it is probable that an impervious rock, concrete, and grout curtain was formed, extending between Buttresses 54 and 56 down to at least Elevation 110. Similarly, grout pipes were left in the higher portions of the tunnel drifts so as to insure, later, the filling, by pressure grouting, of any air pockets left in the higher sections. The same grout pipes served to allow the escape of confined air while the main concrete was being placed. The concrete was carried to a considerable height in the shafts previously mentioned and, because of its slushy consistency, undoubtedly created considerable pressure throughout the drifts. Pressure-grouting was not applied until the concrete had set for a day. The east core-wall was extended approximately 24 ft. farther east. Both the old and new portions of the core-wall were built up to Elevation 142.5, to correspond with the top of the new parapet.

Drainage.—In the original structure the intermediate flooring of each bay had 4 by 12-in. weep-holes. A number of these holes existed at each edge of the main buttress footings, the shorter dimension of the holes being parallel to the footings. The weep-holes were in

pairs, one hole at each edge of the intermediate flooring; the pairs were about 8 ft. from center to center, though the spacing was closer at the up-stream ends of the bays. As a matter of fact, a considerable number of these weep-holes were found to be clogged with concrete which had evidently flowed under the weep-hole forms at the time the original footing or flooring concrete was being placed. Apparently, it had not been thought necessary to provide deeper drainage for the foundation soil.

In planning the reconstruction of the dam, however, it was concluded to provide more positive means of drainage. The system adopted for that portion of the original structure which remained intact differed from that adopted for the new spillway section:

1.—Drainage of Foundation Soil.—In the preliminary plans for reconstruction, the writer proceeded on the theory that the more drains the better, and especially the more positive, the relief of uplift pressure. Consequently, it was proposed in general to extend three drains per bay into the foundation soil. These drains were to consist of perforated pipes such as used in the system of drainage finally adopted. The up-stream drains were to be inclined, and thus were to extend to within about 5 ft. of the down-stream face of the cut-off wall and to a depth of about 5 ft. below the bottom of the new "heel". The middle and down-stream drains of each bay were to be vertical, at distances of about 20 and 30 ft., respectively, from the cut-off wall. At the seven bays of maximum height it was proposed to place the up-stream drains 7½ ft. from center to center transversely, thus providing two up-stream drains per bay. It was also proposed to keep all the original weep-holes open through the original concrete and the concrete of the footing strengthening.

On the other hand, the system of drainage finally adopted, though utilizing the same methods as proposed in the preliminary plans, differed as to the number and location of drains. It was based on two main considerations, namely:

(*a*) The necessity of relieving serious uplift pressure; but, also,

(*b*) The inadvisability of facilitating percolation through the foundation soil.

It was concluded that deep drains might be harmful in earth foundations under circumstances where they would not be harmful

in rock foundations, because, in the former, they might actually facilitate the flow of water by providing artificial channels where previously there was no channel at all. Especially might such results follow if the deep drains were to extend close to the bottom of the cut-off wall.

A consideration of secondary importance was the effect of the low values of the coefficient of frictional resistance assumed in the reconstruction design. Manifestly, a given uplift pressure reduces the margin of safety against sliding by a less amount where there is a low coefficient of frictional resistance than it does where the coefficient is relatively high. It was believed to be preferable, therefore, to take such risk as might result from the existence of pockets, as it were, of unrelieved uplift pressure near the down-stream side of the cut-off wall rather than to invite further leakage by tapping such relatively harmless, deep-lying pockets of water under pressure.

In consequence of these considerations, a system of drainage was adopted which involved but a single deep drain per bay for the higher sections of the intact portions of the original structure, resting as they do on clayey foundation soil. The positions of the drains are indicated in the typical sections of Plates IX and XII. From the former it is seen that the deep drains for the foundation soil extend from Bays 20 to 47, inclusive. The drains consist of 3-in. wrought-iron pipes, perforated with four $\frac{3}{8}$-in. holes per linear foot, one hole in each quadrant. Pipe drains, rather than unlined holes, were adopted for the foundation soil, in order to make the drains relatively permanent, and also because unlined openings would not resist erosion of the foundation soil by leakage water.

The deep drains are about 20 ft. down stream from the cut-off wall, except at the bays of lesser height, where they are at a minimum distance of 12 ft. from it. The drains ordinarily extend to a depth of 5 ft. below the bottom of the new "heel", though they were limited to a depth equalling two-thirds of that of the cut-off, measured from the bottom of the original footing to the bottom of the underpinning, if any, of the original cut-off. They were sunk in lengths of 12 ft. or less. Flush-joint piping was used, so as to avoid couplings or other projections; the latter might leave an annular space around the drains to serve as an outside channel for flowing water without the protection of a metal lining.

Great difficulty was experienced in sinking the drain pipes, primarily because of the boulders encountered in the foundation soil. Various methods were tried, among them the process of jetting, that is, of sinking a drain pipe, open at the lower end, by using a jet of water under pressure playing on the soil inside the pipe near its lower end, so as to allow the pipe to be forced down by hammer blows at the top.

The most satisfactory method, however, and that generally adopted, involved the use of a pile-hammer. For this purpose a McKiernan-Terry, No. 2, pile-hammer was placed on the job and operated either by air or by steam at a pressure of about 80 lb. per sq. in. In order to facilitate driving, the blacksmith on the work fitted the drain pipes with solid points made from pieces of old steel shafting, approximately 3 in. in diameter. The points were welded inside the ends of the pipes, with results as shown in Fig. 19. This figure shows also the perforations in the pipes. It is to be admitted that the perforations were probably clogged with clay to a certain extent as the pipes were sunk. On the other hand, any considerable hydrostatic pressure near the drain pipes would soon open the perforations.

A simple wooden cap prevented injury to the pipe, and the flush-joint pipe did not prove so weak at the joints as to buckle or otherwise cause trouble. In a number of instances, however, boulders proved to be impassable obstacles, and in such cases pipes were driven at near-by locations. In each instance the drain pipes were sunk through the weep-holes of the original structure. The process was necessarily slow. Sometimes it required 12 hours, and even 24 hours, to drive a pipe to a depth of 20 ft.

In general, the deep drain pipes were encased in grout or concrete through the footings and for a depth of about 18 in. below the footings, with the object of keeping the water percolating through the deeper foundation soil separate from leakage water manifesting itself immediately under the footings, and finding its origin perhaps through the cut-off wall. Thus the deep drains are enabled the better to perform their function as detectives, so to speak. The upper ends of the drain pipes were threaded and left exposed for at least 3 in., so as to allow the pipes to be capped or to be connected to pressure gauges. The pipes, of course, were thoroughly cleaned out after they were driven. Very few of the deep drains showed leakage after the work of reconstruction was completed, and none showed any considerable leakage.

Further, under the adopted system of drainage, the two up-stream pairs of weep-holes in each bay were plugged with concrete in connection with the pouring of the triangular section of concrete at the junction between deck and footings. About one-half of the remaining weep-holes—distributed as uniformly as practicable—were left open.

As the reservoir refilled during the latter part of the work of reconstruction, leakage appeared at weep-holes in Bays 51 and 36. At first it was thought that possibly the leakage at Bay 51 was caused by ground-water, perhaps from the water being fed into drill hole 10 (Plate IX) which was being sunk at the time. However, by coloring the reservoir water immediately up stream from Bay 51 with potassium permanganate, it was finally proved that the leakage came through the cut-off. Probably it was due to inadequate bond along a horizontal construction joint in the new "heel", within a foot or two in elevation of the old construction joint at the top of the cut-off wall. The leakage was practically stopped by the simple expedient of dumping clay into the reservoir over the new "heel" from a float extending out from the east shore.

It is probable that in time the leak at Bay 51 would have sealed itself, as has since become true of the leak at Bay 36. In the latter instance the same remedy was applied as at Bay 51, and fine cinders, as well as clay, were dumped from boats into the reservoir water over the "heel". The cure, however, was not effected in this manner; but it was noted that the leakage was gradually decreasing, even though the water level of the reservoir grew higher, until by November 1st, 1915, there was hardly any leakage at this point.

If the leakage at these two points was due to carelessly treated construction joints in the new "heel", the stopping of the leakage may in turn have been due—in part, at least—to the taking of some of the horizontal thrust by the new "heel", with consequent tightening of the construction joint by reason of the compression caused in the up-stream portion of the "heel".

Other leaks, of a minor nature, which appeared in the original portions of the structure have stopped or are stopping themselves in the same manner. Thus on May 25th, 1915, there were eighteen leaks or traces of leakage from weep-holes or drain pipes in the foundation soil, whereas, by November 1st, 1915, there were only three, and these the attendant designated as "traces". In no case

has a pressure test indicated a head of more than 2 ft. above the tops of the weep-holes or drain pipes.

At times certain of the drainage openings yielded muddy water, instead of the normally clear water. In the opinion of the writer, these phenomena, usually temporary, were due to adjustments in the foundation soil caused by increases in loading as the reservoir refilled. In a few instances such openings were grouted shut, rather than take any chances of harmful erosion under the footings.

It may not be amiss to refer here to another phenomenon, namely, that in a number of pipes which are sealed into weep-holes and communicate through the footings into the foundation soil, the water level remains practically at the top of the pipes, which are about 2 in. in diameter and extend about 6 in. above the top of the concrete footings. These pipes do not actually weep, except in the sense that when water is dipped out of the pipes, they refill in a day or two, but again do not overflow. The possibility is indicated that capillary tension over the surface of the ground-water rising in the pipes is sufficient to prevent overflow, but the writer has been unable to advance any explanation which is satisfactory to himself.

2.—Drainage of Rock Foundation at New Spillway.—In the case of the shale forming the foundation for the buttress footings of the new spillway, there is, of course, no danger that deep drains will facilitate erosion of the foundation. This is especially true because of the fact that the shale contains practically no lime which might be taken out in chemical solution. Moreover, as described in detail under the heading "Geological and Foundation Conditions", the rock contains water-bearing seams, and it was possible that ground-water communication might exist between the reservoir and certain springs which appeared in the area excavated for the new spillway footings. Hence it was concluded to provide more drains at the new spillway than in the foundation soil under the intact portions of the original structure.

The system of drainage provided at the new spillway consists in general of three deep drains per bay, placed as shown in the typical sections of Plate X. The drains were sunk with the Calyx, shot-drilling apparatus. In the bed-rock they remain unlined. Above the shale, however, 4-in. pipes were sealed as well as possible into the rock and carried up at least to Elevation 96, in order that leakage

might be detected above the level of the water which ordinarily stands in the new spillway bays as high as the elevation of the horizontal drain through the foot of the spillway apron (Plate X). It was practically impossible to prevent the continuously flooded condition of the space between the new spillway footings; at the same time, this condition has the merit of preventing disintegration of any shale by exposure to the atmosphere.

The up-stream drain of each trio extends down to Elevation 70, well below the bottom of the combination cut-off and anchoring wall. The middle and down-stream drains extend down only to Elevation 75, which elevation also is below that of the bottom of the cut-off. The number of drains was increased at Bays 11 and 12, being the two most westwardly bays of the new spillway; and, inasmuch as the strata slope upward toward the west bank, it is probable that the rock-water, following the dip of the strata, will be intercepted at these bays.

Ever since the deep drains of the new spillway were sunk there has been a flow of rock-water in Bays 12, 13, 16, and 19. However, both the quality of the water and its relatively constant yield prove that there is little, if any, direct communication between such rock-water and the reservoir. The reservoir pressure doubtless has some influence on the rock-water in question, for there was a minor increase in the yield as the reservoir gradually refilled. Yet it is also true that during "dry" periods the rock-water yield has decreased somewhat, even though during the same periods there was but little fluctuation in reservoir level. The maximum rock-water pressure, measured at the tops of the new spillway drains, was equivalent to a head of about 2 ft. The drains overflow freely into the surrounding pools of water.

In view of the drainage system provided throughout the higher portions of the structure, it appears reasonable to assume that, if the drains are not frozen shut at times when uplift pressure may be accumulating under the footings, no serious uplift pressure is to be feared. The assumptions of uplift pressure under the "most severe conditions within the limits of reason", as set forth in Table 3, are based on the drainage provision above described.

Curtain-Wall and Roof.—It was primarily to prevent any considerable freezing at the top of the weep-holes and deep drains throughout the higher bulkhead sections of the dam that a curtain-wall and roof were constructed, as illustrated in the typical section *B-B* of Plate XII.

Manifestly, an ice plug, say, 6 in. deep, at the top of a weep-hole or drain pipe, would for practical purposes serve to confine water under the footings as effectively as though the openings had been filled with concrete and made a part of the footings.

It is believed that, as the result of housing in all bays having deep drains, namely, Bays 11 to 47, inclusive (Figs. 16 and 17), the temperature of the corresponding footings will be prevented from falling to more than a few degrees below the freezing point. During cold weather the radiation of heat outward through the curtain-wall and roof will be largely counterbalanced by the radiation upward of heat from the unfrozen foundation soil and by the further radiation of heat from the reservoir water through the deck of the dam into the enclosed space. Water is at its greatest density at about 39° Fahr., with the density gradually decreasing as the temperature decreases to the freezing point. Consequently, water in the reservoir under an ice covering is at least several degrees above freezing temperature; the difference may be as great as 7 degrees. The assumption made as to the effect of the curtain-wall and roof is supported by observations said to have been made at various hollow dams which are provided with both deck and apron, thus being entirely enclosed. It is reported that at some such structures freezing does not occur in the enclosed portions.

As soon as practicable in the late winter of 1914 the writer had maximum and minimum thermometers placed in the old spillway section of the Stony River Dam, and had the larger openings into that section closed so as to allow a series of records to be made, covering exterior and interior temperatures. Conditions were not favorable for conclusive results, because the reservoir, of course, had been emptied at the time of failure, thus exposing both apron and deck to the cold, with the result that the only source of heat was the foundation soil under the old spillway. Nevertheless, even these observations showed clearly that variations of temperature inside the enclosed spillway section were far less than the corresponding variations in outside temperature; also, that periods of relatively higher and lower temperature inside the structure lagged considerably behind the corresponding periods of relatively higher and lower temperature outside.

During the winter of 1915-16 the lowest temperature within the enclosed portions of the dam was + 26° Fahr., and the lowest exterior

temperature was — 12° Fahr. Under these conditions ice formation has taken place, but not of a serious nature. At the very least, the enclosing of the bays enables the attendant to inspect carefully the drainage system, regardless of weather conditions, and also protects the operating mechanism of the outlet gates. When ice forms within the enclosed portions, the attendant can readily keep it broken or cut away so as to prevent any harmful results.

A portion of the curtain was constructed in the form of a roof, instead of continuing the wall vertically to intersect the deck, in order to avoid enclosing what would have been a triangular section at the top, exposed to cold air on the down-stream side and frequently to the ice covering of the reservoir on the up-stream side. For the bulkhead section between the old and new spillways, the curtain-wall was made 12 in. and the roof 7 in. thick, and, for the eleven bays immediately east of the old spillway, the thickness of the curtain-wall was reduced to 6 in., the roof remaining 7 in. in thickness. At the base of each curtain-wall there is an opening, about 12 by 18 in., fitted with a wooden flap door, as shown on Plate XII, so as to allow the outward flow of any leakage water, but at the same time to keep air currents and snow out of the enclosed space. Wooden ladders bolted to the buttresses are provided between the walkway and the floor at each enclosed bay.

In addition to this primary purpose, the curtain-wall and roof furnish effective lateral stiffening for the buttresses. The writer does not suggest that the bracing of the buttresses in the original structure was insufficient, yet he confesses that he feels better satisfied with the buttresses braced by the curtain-wall, especially as regards the lower portions of those of maximum height, where originally an additional lower set of horizontal brace-beams might have been desirable.

Furthermore, the curtain-wall tends to equalize deflection in the foundation soil under the footings, and, consequently, to shift the load from weaker to firmer soil. Finally, the curtain-wall was utilized in a minor way in the design of the strengthening of the intermediate flooring, allowing, as it did, the omission of transverse reinforcement for a reasonable distance on each side of it.

Excepting for these secondary functions of the curtain, it would have been well to make the wall and roof hollow, for instance, by the

use of cement plaster on metal lath. A hollow construction could have been obtained with concrete, of course, but at a sacrifice of economy. Hollow construction would have better conserved the heat available for warming the enclosed portions of the bays. Relative to this it is interesting to note that more freezing has taken place in the eleven bays immediately east of the old spillway, where the curtain-wall is only 6 in. thick, than in the remainder of the enclosed bays, where the wall is at least double that thickness.

Leakage in Superstructure.—At the time of failure there were pronounced leaks at certain contraction joints in the deck. In the type of construction used the deck slabs are not in contact with each other at the buttresses. Instead, a tongue, integral with the buttresses and varying from 18 to 24 in. in width, separates the slabs. Contraction joints exist, therefore, between these tongues and the slabs, over all buttress haunches. It appears that, in the original construction, insufficient care was taken in forming these joints, with the result that in most cases they did not fulfill their intended functions, and contraction cracks occurred only at intervals averaging about 75 ft. The tenacity of the bond in certain of the intended joints is well illustrated in Fig. 5, which shows the deck of Bay 18 overhanging westwardly for a distance of about 13 ft., the adjacent Buttresses 17 and 16 with their intermediate deck having fallen away due to the undermining of the buttress footings. Naturally, such joints as did act opened excessively and allowed considerable leakage to take place.

The worst leakage of this kind occurred on the east side of Buttress 29, where, during the severely cold weather obtaining at the time of the failure, ice formed to such an extent as to block the stairway leading from the walkway down to the outlet gate-operating mechanism. It was considered impracticable to attempt to reconstruct all the contraction joints so as to make them perform properly their intended function. Instead, all joints which were acting too freely were made as nearly water-tight as possible by cleaning them out thoroughly, packing them with tar-paper placed on edge, and then pouring in hot asphalt. The asphalt has a tendency to flow from the joints during extremely hot weather, but it is believed that such asphalt as remains in the joints, together with sediment deposited by leakage water, will prevent any serious leakage. As a matter of fact, the joint at Buttress 29 still leaks somewhat, especially in cold weather. However, by

reason of the bay being enclosed by the curtain-wall and roof, the attendant can now with little difficulty clear the stairway of the trifling quantity of ice that forms during severely cold weather.

In the new spillway section precautions were taken to insure positive action of the contraction joints by covering the entire surface of such joints with two thicknesses of three-ply tar-paper, or the equivalent thereof. The leakage here has been inconsequential.

Miscellaneous Problems.

Strength of Decks and Buttresses.—In the case of the greatest flood reasonably to be anticipated, the deck of the original structure would be subjected to greater loading than that for which it was designed. The resulting increase in stresses would be greatest at the bottom of the upper lift of the deck, namely, at Elevation 126. Here the maximum stresses with head-water at Elevation 142.25 would be approximately 22 000 lb. per sq. in. in the reinforcing steel and 800 lb. per sq. in. in the concrete. The original steel is reported to have been purchased under a guaranty of 55 000 lb. per sq. in., minimum elastic limit, and the concrete was of a character warranting the assumption of an ultimate strength of at least 2 000 lb. per sq. in. in 90 days.

Under these conditions, it did not appear necessary or advisable to strengthen the decks of the original structure. Likewise, it was not considered necessary to strengthen the buttresses, other than to give them the benefit of the incidental stiffening provided by the curtain-wall previously described.

At the new spillway section, on the other hand, it was considered proper to design the deck for a loading due to head-water at Elevation 142.25, notwithstanding the fact that the new spillway deck thus has greater strength than the deck of the original portions of the structure. Also, the thickness of the buttresses was increased, as compared with the original structure. Above Elevation 112 the increase in thickness was a minimum of 4 in., and below that elevation a minimum of 6 in. Furthermore, the new buttresses are more heavily braced laterally than in the case of the original construction. The walkway slab is thickened so as to serve as a brace-beam, with its principal dimension horizontal, and two other brace-beams, with their principal dimensions vertical, are provided lower in the structure. Detailed comparisons may be made by examining the data on Plates X and XII.

Increase in Storage Capacity.—In view of the much larger spillway capacity provided in the reconstruction, it appeared logical to make temporary use of some of the depth over the spillway by providing increased storage capacity. It was concluded to be feasible to utilize in this way approximately 3 ft. of the 6 ft. 6 in. available depth over the main spillways. Such use for storage purposes, however, is temporary only in the sense that, during extraordinary floods, the entire depth over the main spillways must be available for flood discharging purposes. The resulting increase in the available storage capacity was approximately 380 000 000 gal., or about 25% (Fig. 10), and it afforded a certain consolation to the owner for the heavy expenditures entailed by the failure and reconstruction of the dam. It may reasonably be said that, even in the case of the original structure, it would have been possible similarly to utilize some of the 3 ft. difference in elevation between the crest of the spillway and that of the bulkhead sections; yet it is equally true that an appreciable quantity of additional storage could have been obtained only at the risk of overtopping the structure during floods.

Flash-Board Supports.—The problem involved in increasing the available storage capacity by about 25% was to provide a temporary dam, in other words, flash-boards, which would fail within comparatively narrow, predetermined limits of loading. Thus, it was imperative that 3-ft. flash-boards should not be overtopped by more than 3 ft. 6 in. at the very maximum. The effect of the use of such 3-ft. flash-boards on the flood discharging capacity of the spillways was carefully considered, and a number of hypothetical cases were worked out. One of these cases, previously discussed in this paper, is shown in Fig. 14, wherein it was assumed that, with the greatest flood reasonably to be provided for, the 3-ft. flash-boards might not fail until the head-water had reached an elevation 5 ft. above the base of the flash-boards. The result of such studies was the conclusion that the use of flash-boards would not affect seriously the maximum flood discharging capacity of the dam as reconstructed.

It was impracticable to provide at small cost reliable means which would cause the flash-boards to fail with head-water 3 ft. over the boards, and yet not fail at lower elevations. On the other hand, it is highly undesirable that the flash-boards should fail under any except the more severe freshets; otherwise the inconvenience of renewing

the flash-boards and of the loss of the 3-ft. depth of stored water would occur too frequently.

Both of these considerations were subservient to a third condition, namely, that the means of lowering the flash-boards or causing them to fail must be absolutely automatic, inasmuch as conditions warranted the employment of only a single attendant, and at the critical time he might be absent or asleep, or might for any other reason not attend to the flash-boards when necessary. Finally, the cost of the flash-board provision and of replacing the flash-boards was necessarily to be made as low as possible.

For the purpose of meeting the foregoing requirements, the writer had about seventy experiments made on steel bars or "pins" to serve as flash-board supports. The experiments were intended chiefly to find a material which would fail at a predetermined stress, but would not allow the pins to bend considerably at lower stresses. It was also desired that, when failure occurred, it should consist in the pins snapping off at approximately the elevation of the spillway crest, thus allowing the crest to be cleared absolutely of all obstruction by the flash-boards and their supports. The experiments were performed in the outlet channel, where, by using the sluice-gates and the previously accumulated head in the partly refilled reservoir, it was possible to duplicate the heads which would exist under actual operating conditions, and hence use flash-boards and supports of the same size as under actual conditions.

A controlling condition was the fact that flash-board sockets had been provided in the original spillway 3 ft. 6 in. from center to center. The same spacing was used for the crest of the new spillway, so as to allow interchange of equipment. The scope of the tests covered various conditions of head, lengths of time during which heads were maintained, and degrees of turbulence (akin to reservoir wave action), as well as various kinds and conditions of steel. Inasmuch as it was desired to avoid the use of pins which would bend, and because of previous experience with wrought-iron pins, it was not thought worth while to spend time in testing pins of that material. However, steel pins were tested, including soft and hard steels. The highest carbon content was approximately 1.40 per cent.

None of the steel pins tested in their natural condition gave satisfactory results. Those made of steel with even as high as 0.90 to

1.10% carbon (railway spring steel) persisted in bending before breaking, whereas steels with higher carbon content, though they did not bend unduly, were erratic as to the head or load at which they broke. This was especially true of tool steels. Practically as a last resort, the writer tried the process of hardening the steel; that is, the pins were heated and then hardened by plunging into cold water. Even under these conditions satisfactory results were obtained only within comparatively narrow limits. The softer steels, of course, would not harden, and the very high carbon steels became the more erratic in their behavior by reason of such hardening. Round pins were used, because of the uniform resistance of pins of circular cross-section, no matter at what point the load might be applied (thus making it unnecessary, in this regard at least, to exercise care in placing the pins).

The most satisfactory results were obtained by the use of open-hearth steel with a carbon content varying between 0.40 and 0.80% and phosphorus and sulphur contents each not exceeding 0.05 per cent. In the hardening process the pins were heated to a "cherry red" before quenching in cold water. The heated portion extended about 8 in. above and below that point in the pin which when in place would be at the spillway crest. As the result of the tests on hardened specimens with such characteristics, it was concluded that 1¼-in. round pins, with carbon content of 0.62 to 0.77%, aiming at 0.72%, and sulphur and phosphorus contents limited as above, would fail at approximately the predetermined point, *viz.*, when the elevation of the head-water was about 4.3 ft. above the main spillway crests, or about 1.3 ft. above the top of 3-ft. flash-boards. It was also concluded that such pins would not be subject to excessive temporary or permanent deflections before breaking.

As it was impracticable to wait for further tests before making the final selection of the supporting pins to be used, two sets were ordered for each spillway, together with a sufficient number of extra pins to allow for making confirmatory tests. Subsequent analysis showed that the pins delivered actually have a carbon content of 0.68 per cent. The flash-board pin sockets in both old and new spillways were adjusted by grout filling to a uniform depth of 18 in. The pins were cut to 4 ft. 6-in. lengths, so as to allow them to project 3 ft. vertically above

the spillway crests. Seasoned spruce planks were used as flash-boards, with an actual net height of 2.78 ft. above the spillway crests.

The final tests, made on pins chosen at random from those purchased for actual service, showed exceedingly satisfactory results. In no cases where the conditions were equivalent to those of actual service did the pins fail at heads of less than 4.0 ft., nor did they longer than momentarily withstand without failure heads of more than 4.6 ft. above the base of the flash-boards. Moreover, the maximum temporary deflection above the top of the sockets, with the head-water at elevations slightly less than that at which failure occurred, was only about 10° down stream from the vertical. In those instances where the head-water was allowed to subside to zero after having very nearly, but not actually, attained the predetermined elevation, the pins showed a permanent deflection or set of less than 3° from the vertical. The results of these tests, made in the outlet channel, showed surprisingly little difference between the effects of turbulent and of still head-water.

The apparent brittleness of the hardened pins is the more remarkable in view of the "qualifying" test to which the pins had been submitted after they had been hardened, *viz.*, they had been dropped from the crest of the dam to the concrete flooring of the outlet channel, a distance of more than 50 ft. In order to make doubly certain that defective bars were eliminated, each pin was dropped twice in this manner. Sometimes they fell across previously dropped pins, thus concentrating the impact at a single point of the pin. Yet very few which were put through this conclusive test were thereby broken. This "qualifying" test was applied, not merely to the pins used for the confirmatory tests in the outlet channel, but to all pins which were placed in actual service.

With regard to the sensitiveness of the pins in question, the results of an earlier test may be of interest. In that test $1\frac{3}{16}$-in. round pins, with carbon content of 0.62%, were used at the regular intervals of 3 ft. 6 in. to support flash-boards about 38 in. high. The head-water was maintained for $10\frac{1}{2}$ hours at an elevation approximately 3.7 ft. above the base of the flash-boards. At the end of that period the head was increased to 4.2 ft., and within a few minutes two of the three pins under test, supporting three panels of flash-boards, snapped off simultaneously at the top of the sockets.

Since the reconstruction of the dam has been completed, the headwater, with the flash-boards in place, has reached Elevation 139.83, which is about 12§ in. over the top, and 3.83 ft. above the base, of the flash-boards. The supporting pins met the expectations, as none failed, despite the fact that they were under severe load for several hours. Subsequently, the flash-boards were taken down for the winter, and it was found that the pins had suffered no permanent deflection.

Underpinning Problems at the New Spillway.—The original footings of Buttress 10, which was left intact and forms the west abutment of the new spillway, were about 22 ft. higher than the footings of the adjacent new Buttress 11, and about 27 ft. higher than the footings of new Buttress 12. The footings of the latter buttresses rest on bed-rock, whereas the original footings of Buttress 10 rested on the clayey over-burden. Evidently, it was necessary to provide secure support for Buttress 10 as well as to insure the stability of the foundation soil under the adjacent (up-hill) portion of the original structure. This was accomplished by underpinning Buttress 10 with a retaining wall founded on bed-rock. In this manner it was possible, in effect, to extend the footings of Buttress 10 down to rock and, at the same time, prevent the lateral displacement of the soil under the adjacent footings. The retaining wall was extended down stream as a portion of the new spillway channel, and decreases in height as the channel swings away from the west bank. It is of reinforced concrete, and is of substantial proportions for a sufficient distance down stream from the footings of Buttress 9 to confine adequately the foundation soil immediately down stream from that portion of the dam, as shown by Figs. 16 and 17.

The type of construction of the underpinning at Buttress 10 is illustrated in Figs. 25 and 26, which show the underpinning in successive stages of construction. To avoid the necessity of temporary shoring under Buttress 10, relatively narrow excavations were first made for the 4-ft. wide counterforts, leaving the intermediate soil to take the weight of the buttress and its overhanging footing (which was not removed). Due to the character of the soil in question, it was impracticable to allow the buttress to be supported in this manner for any considerable length of time. Fortunately, no severe rains occurred in the meantime, and the counterforts were constructed without mishap up to the bottom of the footings. Then, by means of holes

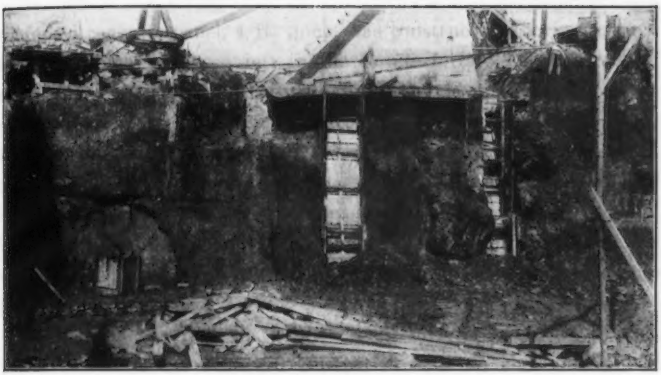

FIG. 25.—UNDERPINNING AT BUTTRESS 10.

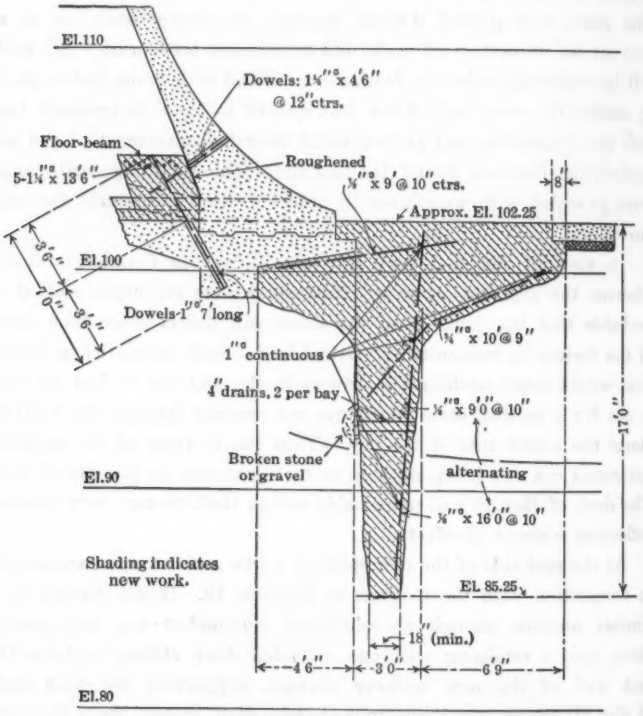
FIG. 26.—UNDERPINNING AT BUTTRESS 10, STONY RIVER DAM.

drilled through the footings, grout was forced between the surfaces of contact. Subsequently, the counterforts took the load without noticeable sinking on the part of Buttress 10.

As soon as the concrete in the counterforts had set sufficiently, a reinforced concrete panel, 4 ft. thick, was constructed, bearing against shoulders which had been left in the counterforts. The concrete in this panel was poured directly against the clayey bank, so as to prevent the formation of voids and consequent settlement. All voids left immediately under the footings were filled with grout, not so much to enable the west half of the Buttress 10 footings to transmit load into the foundation soil as to prevent lateral displacement of the soil underlying Buttress 9 and its footings. The retaining wall panels were provided with weep-holes in order to drain adequately the supported soil.



In view of the fact that Buttress 10 now is founded on rock, whereas the adjacent westward Buttress 9 rests on clayey soil, it is probable that the footings of the latter will deflect more than those of the former in transmitting vertical load. Such inequality in deflection would cause undesirable stresses in the footings of Bay 10 were it not for a vertical seam which was cut entirely through the flooring, along the center line of the bay. Thus the footings of the adjacent buttresses can act independently as far up stream as the cut-off wall. The deck of Bay 10 will presumably adjust itself to any such unequal deflection without ill effects.

At the east side of the new spillway a like problem was encountered in connection with the footings of Buttress 19. It was treated in a similar manner, though an additional counterfort was constructed. Here, too, a retaining wall was extended down stream to form the east wall of the new spillway channel, supporting the west flank of the fill which was made immediately down stream from the dam between the old and new spillways.

Toe Protection at Old Spillway.—The channel down stream from the old spillway has a concrete mat 9 in. thick, the mat having been placed on crushed stone which covered the original ground surface to a depth of 4 in. In the reconstruction it was felt that, considering the possible effects of frost, in the way of heaving the channel mat, and of scour at the down-stream end of the mat, such

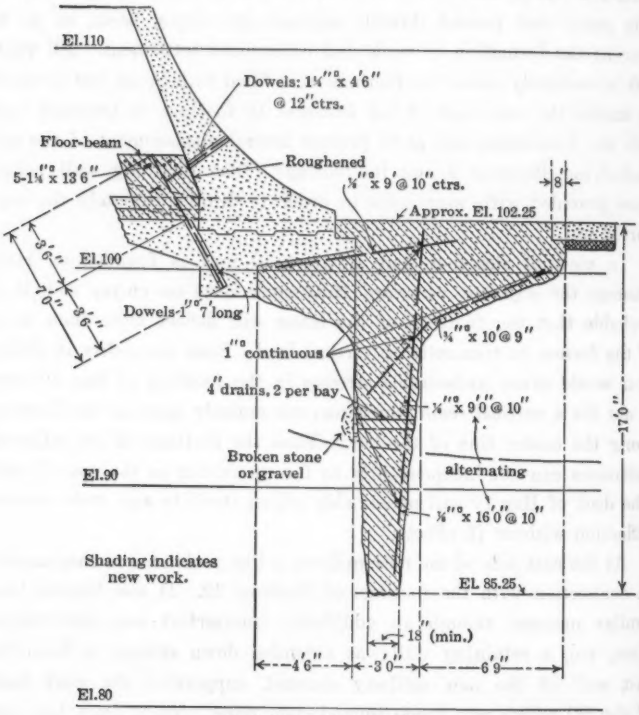
construction could hardly be considered permanent, and it appeared to be wise to make more substantial provision.

This took the form of additional toe protection, rather than of doing away with the original channel mat and substituting a relatively expensive, heavier mat. The principal features of such toe protection are shown in Fig. 27. The row of 10 by 10-ft. mat slabs immediately down

TOE-WALL AT OLD SPILLWAY
FIG. 27.

stream from the old spillway apron bucket was taken out, and excavation was made for a toe-wall extending to a depth of 17 ft. below the top of the channel mat or hearth. This toe-wall was designed to act as an anchoring wall, similar in this respect to the anchoring walls provided for the bulkhead portions of the original structure. However, it was carried to a greater depth, in order to prevent the undermining

of the main footings of the old spillway in case the channel mat should be washed away in whole or in part.



Here, again, the toe-wall forms, in effect, an extension of the original footings. Its load is received through the original toe of the spillway. However, because the apron of the spillway had been cast separately from the footings and the buttresses, it was impossible to utilize the apron, as originally constructed, to transmit any load into the toe-wall, except in so far as the weight of the apron and the frictional resistance, along the surfaces of contact between the apron and buttresses, were concerned. It was found advisable to utilize the apron to a greater extent by constructing a so-called floor-beam, as shown in Fig. 27, and tying the apron into the floor-beam with the steel dowels there shown. This arrangement also served the purpose of distributing the load on the base of the buttress over a greater distance (up and down stream), thus reducing the unit load on the concrete in proportion.

In addition to the deep toe-wall, wing-walls were extended down stream, as shown in plan on Plate XI. The inner end of each wing-wall extends to the same depth as the toe-wall, but the outer ends are approximately 11 ft. deep below the top of the mat. The wing-wall at the west end of the old spillway was capped by the concrete of a wasteway, which allows any excessive head of water in the channel immediately down stream from the bays of maximum height to relieve itself into the old spillway channel. The new fill between spillways has been protected on its east flank along the old spillway mat by the construction of a wall of sandstone boulders laid in cement mortar.

Anchoring Wall at Heel of Gate Sections.—At Bays 30 and 31 the openings from the reservoir to the outlet gates prevented the construction of the standard type of "heel" shown on Plate XII. The upper cantilever member of the anchoring wall would have interfered with the opening. Therefore, a modified method of construction was used, as shown on Plate XIII. In this case the anchoring wall extends from the top of the concrete protection mat, immediately up stream from the gate openings, to a depth of about 15 ft. below the original footings. The cantilever arms are not so long as in the standard "heel", for the reason that the tie-steel enters the anchoring wall at the middle, inclining downward from the original footings. The steel bars find embedment in the new concrete immediately adjacent

construction could hardly be considered permanent, and it appeared to be wise to make more substantial provision.

This took the form of additional toe protection, rather than of doing away with the original channel mat and substituting a relatively expensive, heavier mat. The principal features of such toe protection are shown in Fig. 27. The row of 10 by 10-ft. mat slabs immediately down

stream from the old spillway apron bucket was taken out, and excavation was made for a toe-wall extending to a depth of 17 ft. below the top of the channel mat or hearth. This toe-wall was designed to act as an anchoring wall, similar in this respect to the anchoring walls provided for the bulkhead portions of the original structure. However, it was carried to a greater depth, in order to prevent the undermining

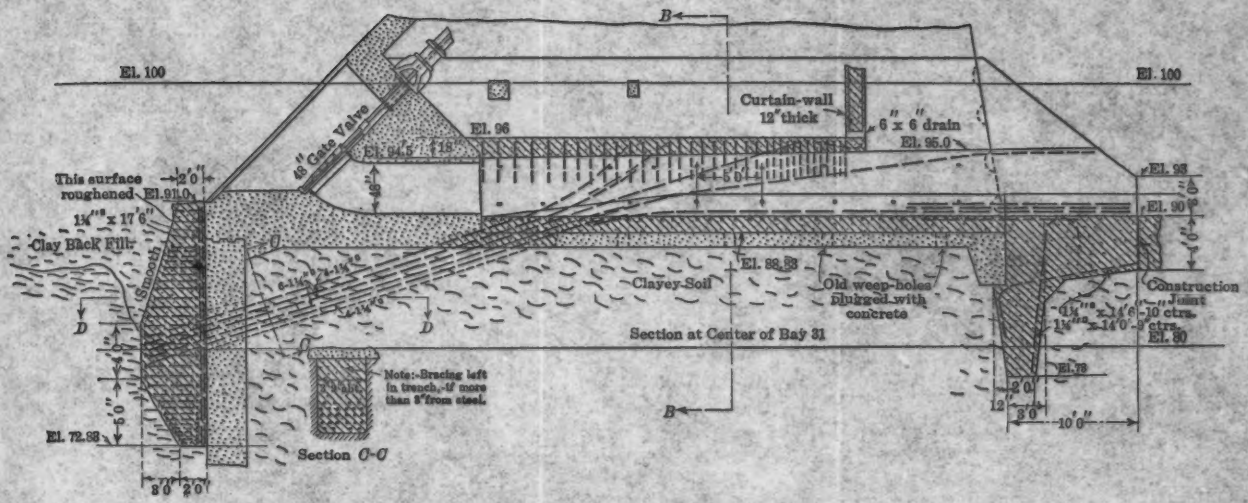
of the main footings of the old spillway in case the channel mat should be washed away in whole or in part.

Here, again, the toe-wall forms, in effect, an extension of the original footings. Its load is received through the original toe of the spillway. However, because the apron of the spillway had been cast separately from the footings and the buttresses, it was impossible to utilize the apron, as originally constructed, to transmit any load into the toe-wall, except in so far as the weight of the apron and the frictional resistance, along the surfaces of contact between the apron and buttresses, were concerned. It was found advisable to utilize the apron to a greater extent by constructing a so-called floor-beam, as shown in Fig. 27, and tying the apron into the floor-beam with the steel dowels there shown. This arrangement also served the purpose of distributing the load on the base of the buttress over a greater distance (up and down stream), thus reducing the unit load on the concrete in proportion.

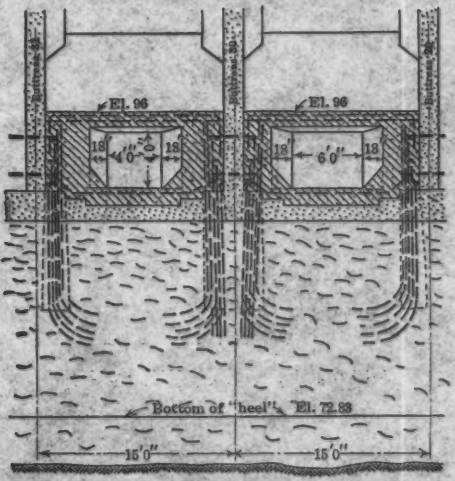
In addition to the deep toe-wall, wing-walls were extended down stream, as shown in plan on Plate XI. The inner end of each wing-wall extends to the same depth as the toe-wall, but the outer ends are approximately 11 ft. deep below the top of the mat. The wing-wall at the west end of the old spillway was capped by the concrete of a wasteway, which allows any excessive head of water in the channel immediately down stream from the bays of maximum height to relieve itself into the old spillway channel. The new fill between spillways has been protected on its east flank along the old spillway mat by the construction of a wall of sandstone boulders laid in cement mortar.

Anchoring Wall at Heel of Gate Sections.—At Bays 30 and 31 the openings from the reservoir to the outlet gates prevented the construction of the standard type of "heel" shown on Plate XII. The upper cantilever member of the anchoring wall would have interfered with the opening. Therefore, a modified method of construction was used, as shown on Plate XIII. In this case the anchoring wall extends from the top of the concrete protection mat, immediately up stream from the gate openings, to a depth of about 15 ft. below the original footings. The cantilever arms are not so long as in the standard "heel", for the reason that the tie-steel enters the anchoring wall at the middle, inclining downward from the original footings. The steel bars find embedment in the new concrete immediately adjacent

to, and bonded into, the lower portions of Buttresses 29, 30, and 31, as shown in Section *B-B* of Plate XIII. The bars were encased entirely in concrete to protect them against corrosion in the foundation soil.



In order to place the tie-steel, holes were opened by blasting through the original cut-off wall, and tunnels were carried upward under the footings to connect with openings which had been cut down through the footings. The bars were then placed and the concrete poured from the interior of Bays 30 and 31. The special construction at these bays was simpler, in so far as the anchoring wall itself was concerned, but was more expensive than the standard type because of the necessity of placing the tie-steel in the manner described.



Outlet Channel.—The outlet channel has been referred to and partly described in preceding portions of the paper. Its purpose is essentially to prevent any scour which might result either from discharge from the sluice-gates or from water flowing over the intermediate spillway which extends the length of the bulkhead section between the old and new main spillways. The sides of the channel are constructed as retaining walls to hold the down-stream fill. Longitudinal and transverse cross-sections of the outlet channel are shown in Fig. 24, and Plate XI shows it in plan. The channel extends a total distance of 64 ft. down stream from the toe of the original structure, and is protected by a cut-off, about 12 ft. deep, penetrating a bed of heavy boulders. The details of this structure are not such as to warrant further description.

A connecting channel was necessarily constructed to lead from the outlet channel directly down stream to the old river-bed. This change of stream channel has a further advantage in that it protects the lower end of the old spillway channel mat from the scour, due to sluice-gate discharge, to which it was subjected under the original construction.

Materials of Construction.

Cement.—The cement for the work of reconstruction, as also that for the original construction, was furnished by the Alpha Portland Cement Company, and all the cement for the reconstruction came from its Lehigh Valley mills. The cement was required to meet the Specifications of the American Society for Testing Materials plus those specifications of the United States Government (Bureau of Standards)

Transverse Vertical Section B-B

ANCHORING WALL AT HEEL OF OUTLET GATE BAYS.

Note:-Shaded portions indicate new work.
All reinforcing and tie steel bars are twisted square.

pertaining to insoluble residue and loss on ignition. It was tested at the mills by representatives of the Pittsburgh Testing Laboratory.

Stone.—Crushed sandstone was used for the concrete aggregate. It was quarried from ledges exposed along the mountain side within convenient distance of the work. Three quarries were opened; two of these required short hauls on the temporary, standard-gauge railroad, and the third furnished rock to the crushers directly by small cars operating on a narrow-gauge track. The cost of quarrying was heavy, inasmuch as the ledges were in no case of great depth, and the cost of stripping was therefore proportionately high.

In view of the relatively high cost of the materials for concrete, sandstone boulders were utilized to as great an extent as possible. These boulders were ordinarily of one-man size, and either were found in the river-bed or were yielded by the excavation for anchoring walls, cut-off extensions, etc. The larger proportion of the boulders was found in the excavations near the middle of the valley.

Sand.—As in the case of the original construction, sand was obtained by crushing and rolling the native sandstone, though the product was not the best that could be desired. Probably the chief defects in the sand were its inferior grading, and especially the large proportion of fines. Nevertheless, the resulting concrete was acceptable, as shown by tests made from time to time on standard specimens cast in most cases from concrete taken directly from the mixer in the regular course of the work. The specimens were shipped to Pittsburgh to be tested.

Steel.—Open-hearth reinforcing steel was furnished by the Carnegie Steel Company, under the June 1st, 1912, Standard Specifications, of the American Society for Testing Materials, for cold-twisted, steel reinforcing bars. Thus the steel was required to show a minimum yield point of 55 000 lb. per sq. in. The standard design data, as used for the cold-twisted bars, may be of general interest, and are therefore submitted in Table 6.

Classes of Concrete Construction.—Four standard classes of concrete construction were used in the reconstruction, and, on the basis of these classes, working stresses for use in design were specified, as follows:

Class A-1.—Reinforced concrete; proportions 1 : 2¼ : 3¾; allowable working stress for steel, 18 000 lb. per sq. in.; for concrete,

TABLE 6.—STANDARD DESIGN DATA FOR COLD-TWISTED SQUARE STEEL BARS.

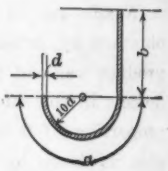
		At 16 000 lb. per sq. in.			At 18 000 lb. per sq. in.		a	b		
		Bond stress, in pounds per square inch.					In inches.	In inches.		
		75 (A-2)	67 (B)	60 (C)	75 (A-1)					
⅜	1½	20	23	25	23	4	12	8	1½ to 6	2
½	2	27	30	34	30	5	16	11	2 to 6	2½
⅝	2½	33	38	42	38	6	19	13	2½ to 10	3
¾	3	40	45	50	45	7½	24	16½	3 to 12	4
⅞	3½	47	53	58	53	9	28	19	3½ to 13	4½
1	4	54	60	67	60	10	32	22	4 to 14	5
1¼	4	67	75	84	75	12½	40	27½	4½ to 16	6

NOTE.—Use no ⅜-in. bars except under especially approved conditions.



Use ½-in. bars only where unavoidable, *e. g.*, for slabs only 6 or 8 in. thick.

As far as possible use bars of same diameter in same portion of structure, so to avoid confusion.

Wherever possible, bar lengths are to be specified to nearest ½ ft.

Bars should not be specified more than 40 ft. long; and ordinarily not more than 30 ft. long.

Use no clamps for splicing unless there is no other recourse.

*These dimensions apply likewise to distance from end of bar to nearest concrete surface. Where bottom of slab is cast on ground, allow 1 or 2 in. extra depth of embedment.

†Where available length for straight embedment is less than 90% of standard length, use 180° bend. (See diagram.) Letters in parentheses refer to classes of concrete.

‡Bars, in general, should not be farther from center to center than the distance from outer compression fiber of concrete to center of steel.

700 lb. per sq. in. This was used almost solely in the footing strengthening, because the protected condition of the concrete there warranted taking advantage of the economy resulting from the highest practicable working stresses.

Class A-2.—Reinforced concrete; proportions 1 : 2¼ : 3¾ (the same as those for the preceding class); allowable working stress for steel, 16 000 lb. per sq. in.; for concrete, 500 lb. per sq. in. This class of construction was used for the deck, apron, and brace-beams of the new spillway; also for all reinforced concrete retaining walls.

Class B.—Reinforced concrete; proportions 1 : 2¾ : 4¾. This class of construction was used where the design was not limited to the bare requirements measured by allowable working stresses,

and where the quantities of concrete were ample. It was used, for instance, in the buttresses of the new spillway, the anchoring walls at heel and toe of the original structure (excepting the toe-wall at the old spillway), curtain-walls and roofs, main parapet of the outside bulkhead sections, floor of the outlet channel, and the heavy mat of the new spillway channel.

Class C.—Plain concrete; proportions 1 : 3½ : 5½. In general, this class of construction had no reinforcement, except for temperature stresses and the like. It was used for the buttress footings and the combination anchoring wall and cut-off of the new spillway, the counterforted retaining walls underpinning Buttresses 10 and 19, all cut-off wall extensions and the toe-wall at the old spillway. In the latter case, especially, as well as in certain other places, considerable quantities of boulders were incorporated in the Class *C* concrete. It was specified that boulders should not constitute more than 40% of the total volume, and that they should not interfere, or be in contact, with reinforcing steel.

Construction Methods and Equipment.

The total quantity of concrete involved in the reconstruction and strengthening work was approximately 10 160 cu. yd., according to the plans; actually, about 11 700 cu. yd. (including boulders) were placed, the discrepancy of about 15% being due principally to over-run in trench excavation. The quantity of concrete reported to have been placed during the original construction of the dam was 11 800 cu. yd. Evidently, the reconstruction was by no means a small matter as compared with the original construction. The quantities involved in each case were less than those which would have been required had a dam of the solid masonry type been constructed; yet the complexities involved in, and the attention to detail required by, the type of construction actually used were very much greater than would have been necessary in the case of a solid dam.

The construction methods were essentially like those used in the original construction work, and described elsewhere.* In view of that fact, it does not seem proper to occupy space in this paper with any detailed description of the construction methods. As a matter of fact,

* *Engineering News*, January 22d, 1914.

certain special methods of procedure applied in the reconstruction have already been described in connection with the discussion of the governing features of design.

Construction Equipment.—As soon as practicable after the writer had been engaged to investigate the foundation conditions and determine the feasibility of reconstructing the dam so as to be safe, work was begun on a standard-gauge railroad connection. This was made, as in the case of the original construction, with the standard-gauge logging railroad of the Parsons Pulp and Paper Company, but at a point nearer the dam site and about 16 miles from Dobbin, W. Va., on the Western Maryland Railroad. The connecting spur added a little more than 2 miles to the distance. It was constructed at a cost of about $3 000 per mile for grading the road-bed, ballasting, cross-ties in place, and laying rails, though not including the cost of the rails.

This low cost was due to the fact that, in the construction of this spur, no pretense was made of keeping curvature and grades within ordinary limits, nor was much attention paid to ballasting the road-bed. The maximum curvature was 31° 15′, and the maximum grade was 12.4 per cent. For a considerable distance the grade averaged 9.8 per cent. The contour of the ground was followed closely, and the greatest part of the work of grading consisted in taking out boulders with which the ground was strewn. Small streams were bridged with tree-trunk stringers or cribbing.

The rails were new, 85 lb. per yd., and were carried on heavy ties, which, however, were spaced at greater than standard distances. After the reconstruction was completed, the rails were taken up and transferred for permanent use by the owner in lumbering operations.

Despite the inferior character of the roadbed, no accidents worthy of note occurred, and the results were such as to justify what might have been an inadequate expenditure for railroad connection, had it not been for the relatively heavy rails. The owner supplied a 42-ton geared engine from its West Virginia lumbering operations, and three of its own standard 40-ft. flat cars which were used principally for transporting rock from the quarries to the crushers. The engine was able to handle one standard loaded box car at a time up the maximum grade. Fortunately, the grade favored in-bound freight.

A Marsh-Capron mixer, of ¾ cu. yd. capacity, steam-engine driven, mixed the concrete and delivered it into buckets of 1½ cu. yd. capacity.

set on flat cars. These cars were run on a narrow-gauge track from the mixer out to a point near the west abutment of the dam and directly under a 3-ton Lidgerwood cableway. The cableway was of 1 000 ft. span, and was used in turn to deliver the buckets of concrete either to hoppers and chutes for distribution laterally and under the deck of the original structure, or, in the case of the new spillway buttresses, into wooden bucket cars which ran on portable, narrow-gauge tracks along the top of the buttress forms, and thus allowed the concrete to be deposited near the ends of the forms. The cableway was also of general utility in shifting equipment and forms, transporting reinforcing steel, etc.

Steam was furnished both from a main plant, consisting of two 100-h.p. boilers, on the west hillside just above the spur railroad track, and also from smaller, individual boilers placed at different parts of the work from time to time, according to immediate needs. Such boilers were especially necessary during cold weather because of the condensation in the long pipe line from the main boiler plant. The walkway through the original structure, and continuing through the new spillway, served as a convenient carrier, on which were placed water, steam, and compressed air pipes, which were tapped wherever necessary. Water was supplied from a duplicate set of steam plunger pumps, which were set up in Bay 30 and took water from a sump fed from the river by the 20-in. sluice-gates.

An 8 by 10-in. compressor proved to be a great utility, especially in connection with the very convenient Ingersoll-Rand "jack-hammer" drills. The latter were used to drill holes in the original concrete, for the purpose of embedding steel dowels, or for blasting—as was especially necessary in cutting out the base of the deck to allow the passage of the tie-steel from the anchoring wall at the heel. These air drills were also used for roughening the original concrete wherever necessary. Operated by steam, they proved only fairly satisfactory for drilling purposes in the stone quarries, but were displaced later by a standard Sullivan steam drill.

For pumping, an 8-in. centrifugal pump and a portable, gasoline-engine driven, 4-in. diaphragm pump, were used as much as possible, but in the deeper trenches steam siphons were used.

Cold-Weather Concreting Precautions.—Concrete was placed throughout the winter of 1914-15 under temperatures as low as 10°

Fahr. The principal precautions to prevent concrete from freezing were: First, the water used in mixing the concrete was heated so that the temperature of the mixed batch, after being away from the mixer several minutes, was about 55° to 75° Fahr. The water was heated by live steam to a temperature considerably higher than that last mentioned because the aggregate absorbed much heat from the mortar of the batch, despite the fact that steam pipes were used in the sand and crushed stone supply bins to heat these materials also.

Secondly, the concrete or earth surfaces against which new concrete was to be poured were thawed out or warmed. This was accomplished with a jet of live steam which at the same time served to clean thoroughly the surfaces of old concrete.

Thirdly, the freshly poured concrete was covered with canvas. The canvas covering was usually arranged so as to leave an air space which, under especially severe temperatures, or with thin concrete, was warmed with coal-burning salamanders or gasoline torches. At times, also, live steam was turned in under the covering until the concrete had attained a sufficient set.

As the result of such precautions, little concrete was frozen. Those surfaces which were frost-bitten were usually in places where the concrete was relatively massive, and precautions had consequently been relaxed.

Cost.—Despite the fact that approximately the same quantity of concrete was placed in the reconstruction and strengthening as in the original construction, the later work was done at a considerably less total cost, due principally to the fact that much of the new concrete was comparatively massive. Nevertheless, the new work required more attention and care than if the work had been entirely of a standard nature and free from the conditions imposed by the existence of the original structure. Only about 25% of the total cost of the reconstruction and strengthening was expended in rebuilding (as a new spillway) the portion of the dam between Buttresses 10 and 19. Had this portion been rebuilt as a bulkhead section, rather than as a new spillway, the proportion of the total cost involved therein would have been even less. The remainder of the cost was expended in strengthening the original structure and in providing features which had not at first been supplied. A considerable quantity of work, especially in the form of

cut-off wall underpinning, was not anticipated at the beginning of the reconstruction.

Due to the facts that the new work was scattered over the entire site and that it was carried on through the winter, the unit costs were necessarily high. The fact that the work did not conform to standards (except in the case of the new spillway superstructure, which constituted a small proportion of the whole) also contributed to such high unit costs. For the same reason, the unit costs are not of general value. Thus the monthly average costs for excavation, exclusive of charges for plant and overhead expenses, varied from $0.51 for new spillway channel excavation to $7.68 per cu. yd. for excavation required for underpinning the original cut-off near the center of the valley. The corresponding costs for concrete varied from $3.40 per cu. yd. in place for Class *C* concrete in cut-off extensions to $13.43 per cu. yd. for Class *B* concrete in curtain-wall and roofs.

The results attained in the reconstruction and strengthening of the Stony River Dam could have been secured at far less cost—undoubtedly less than half the cost of reconstruction—had the features involved been incorporated in the original construction.

Personnel.

In his capacity as Consulting Engineer in charge, the writer made inspection trips to the work about twice each month, after the reconstruction had been begun in earnest. Mr. D. N. Showalter represented the writer as Resident Engineer throughout the entire reconstruction. Mr. C. W. Hotaling was Superintendent of Construction, having filled the same position for the Ambursen Hydraulic Construction Company after it took over the original construction work in March, 1913.

The writer desires to take this opportunity to express his appreciation of the whole-hearted co-operation of Messrs. Showalter and Hotaling, as well as of the executive officers of the West Virginia Pulp and Paper Company, owner; also to acknowledge the valued advice of Daniel W. Mead and C. V. Seastone, Members, Am. Soc. C. E., with whom he was privileged to consult on several occasions during the period of reconstruction.

DISCUSSION

Mr. Ledoux.

J. W. LEDOUX,* M. AM. SOC. C. E. (by letter).—Mr. Scheidenhelm has written a very exhaustive treatise on the reconstruction of the Stony River Dam. As a result of his work he has formed two important conclusions with which the writer heartily agrees and has been advocating for a great many years, namely, that most masonry dams fail due to sliding, and that too little provision is made for excessive floods.

Heretofore, the engineer was considered conservative when, on a small water-shed, he provided for a flood of 250 ft. per sec. per sq. mile, but floods of several times that size are likely to occur, and it is only a question of time before they do.

Whether provision should be made for the greatest possible flood that will probably occur at intervals of a calculated number of years involves several questions:

First.—Complete provision should be made, if otherwise lives may be lost.

Second.—If only damage to property and the structure itself is involved, then it becomes a question of whether the cost of making complete provision is greater or less than that of the damage when figured on a present-worth basis. For instance, if a dam is seriously overtopped once every 50 years, causing a wash-out which is estimated to cost $20 000 to repair, and the cost of making complete provision to prevent that overtopping would be $10 000, the present worth of $20 000 to be spent 25 years later at 5% is about $6 000; so, on this basis, it would be engineering prudence to take a chance, provided no other inconvenience or damage were entailed than the $20 000. It involves great expense in many cases to make provision to take care of a flood equal to 1 600 sec-ft. per sq. mile. Small water-sheds in the eastern part of the United States, however, are subject to such floods at very rare intervals, and that means a flow corresponding to a continuous rainfall of about 2½ in. per hour.

The writer visited the Stony River Dam a few days after its failure. The following is an extract from his report made at that time:

"The caretaker, Mr. Kerr, who lives with his wife at the house close to the dam, stated that on Wednesday morning, January 14th, about nine o'clock, he noticed water coming through muddy on the down-stream side of the dam at the point where it subsequently failed. By Wednesday night this had become much worse, and on Friday morning at 1 o'clock he notified Mr. Allen Luke, one of the members of the firm of the West Virginia Pulp and Paper Company, that he was afraid the dam was going to break. He was told to open the gates located on the inside of the dam. He stated to his people that these

* Philadelphia, Pa.

gates could not be opened on account of the stairway leading to them being covered with ice, the temperature being below zero. Mr. Ledoux.

"By 2.30 A. M. conditions had become so grave that he notified by telephone the town of Maysville and others located down stream along the banks of the Stony River and Potomac. The water was rushing through the large and increasing space underneath the dam, and by Thursday morning at 9 o'clock the water had fallen in the dam 3 ft. At 9.30, two bays, or 30 ft., broke down, and in half an hour three more failed. By 11 o'clock the water was about 13 ft. below the spillway, and by 6 P. M., only 4 or 5 ft. of water remained in the dam. By Friday morning it was entirely empty.

"The dam was built on a clay formation and under the up-stream toe was a cut-off wall, from 3 to 4 ft. thick. For a distance of 600 ft. or more, on the east side of the valley, this cut-off wall extended down to rock, which, from all accounts, is of an indifferent quality, characteristic of the bituminous coal formation in the vicinity of the Middle Kittanning. The cut-off trench proved to be very difficult, due to its depth, the number of boulders encountered, and water-bearing soil, so that the material sometimes caved behind the shoring and made the work dangerous. The engineers in charge of the work figured that a considerable amount of money could be saved by not continuing on rock, which appeared to be increasingly difficult to reach toward the west end, and so notified the principals of the Paper Company. Not wishing to take any chances, the Company advised a conference with able consulting engineers, which was had, and it was decided to step up the cut-off wall until it had a depth of about 5 ft., and, according to information given me by the Superintendent of the Whitmer Lumber Company, these engineers concurred in the recommendation of the local engineers that it would be safe to make this change, on account of the quality of the material being very compact clay, sand, and gravel.

"At the west end of the break, this cut-off wall was not more than 5 ft. deep and about 2½ ft. in thickness. The break extended from Abutment 11 to Abutment 16, and the dam is further damaged to Abutment 19. The stepping up from rock to earth began suddenly between Abutments 15 and 16, the first step being about 11 ft., and at Abutment 11, the bottom of the cut-off trench was more than 20 ft. higher than it was at Abutment 16. It is quite probable that unequal settlement occurred due to the change from rock to earth, as this is where the break took place, and it is hard to understand how engineers familiar with the Austin Dam failure could have consented to any such curtailment of depth of the cut-off trench.

"The writer does not think that the failure of the dam was due to the Ambursen type of superstructure, but it is very clear that, with this type, it is no more safe to economize on the depth of foundation than with any other, because if it is built on an earth foundation and water can flow through under it in material quantities, failure is certain to take place.

"The strongest claim of the advocates of the hollow dam, particularly the Ambursen, is that it is much more economical than the solid gravity type, but, as a matter of fact, on account of its structural complication, with its forms, reinforcement, and necessity of more expensive concrete, it costs not much less for equal stability and utility;

Mr. Ledoux.

but, in order to make the comparison more favorable to their type, they economize in the foundations, which, in the writer's judgment, should be as thoroughly taken care of as with the gravity dam. The case in point is certainly a flagrant illustration of their bad judgment in this respect.

"According to the plans of the dam revealed in a paper presented by Mr. Bayles in *Engineering News*, of January 22d, 1914, it is going to be a very difficult matter to decide just how far to carry the repairs so as to prevent subsequent failure of some other portion.

"It is the practice of conservative engineers never to build a masonry or concrete gravity type of dam unless they can found it on rock for practically the entire distance, and, in addition thereto, it is the practice to carry a cut-off wall down far enough underneath the main foundation to be practically impervious to water. The writer does not see what advantage the Ambursen type of construction possesses which makes this requirement unnecessary, but, in the case of the Stony River Dam, none of the main structure was founded on solid ledge rock and only two-thirds of the cut-off trench.

"Fortunately, no lives were lost, but that was probably due to the gradual emptying of the dam. If the break had taken place suddenly, when the dam was full, like that at Austin, Pa., it is probable that there would have been some loss of life, although the towns were far enough down stream so that they could be notified by telephone at least an hour before the water reached them.

"From an inspection of the construction, which is very readily made from a concrete walk, running longitudinally within and throughout the entire length of the dam, the writer is convinced that the superstructure was built in a workmanlike manner, but the concrete appears to be somewhat softer than it should, according to the best practice. On account of the large amount of snow all around and the débris in the valley on the down-stream side of the dam, and the ice on the up-stream side, it was impossible to make any close inspection of the soil or the geological formations.

"In one of the bays are several gates for letting off the water in case of emergency, or for any other reason, and there is also in an adjacent bay a large gate for the same purpose. An archway entrance goes through the wall between these two bays. At the side of one of them is a concrete stairway and an iron hand railing, and this, at the time, was covered with ice, due to drippings from a crack in the up-stream portion of the dam, making the valves inaccessible. A casual inspection, however, showed that this ice could have been chopped off with a hatchet or axe in a few minutes, or poles or a ladder could have been run down from the concrete walk to the floor where the valves were located in the adjacent bay. If these gates had been opened wide from Wednesday morning, it is quite probable that the water in the dam would have been so lowered as to prevent failure. It is better, however, for the engineering profession, that the dam did fail, as it will further impress upon their minds the necessity of care and thoroughness in the design and construction of dams in general.

"The nature and abundance of suitable soil and the depth of the bed-rock indicate that the proper type of structure would have been an earthen dam with a concrete spillway on either the east or the west

side-hill, and this could probably have been built safely at as low a cost as the type that was adopted." Mr. Ledoux.

J. K. FINCH,* ASSOC. M. AM. SOC. C. E. (by letter).—When the failure of the Stony River Dam was first reported, and before complete details were available, the writer pointed out† that dams of this type were particularly weak as regards sliding. Articles on the inclined slab and buttress dam always emphasize the great stability of these dams against overturning, but fail absolutely to call attention to their weakness as regards sliding. When the buttresses extend down to rock, the rock surface should be roughened and the buttress well bonded to it. When the dam is founded on a spread footing, four important points must be considered. Mr. Finch.

1.—The material just below the floor of the valley, on which the spread footing between the buttresses is placed, must be of a satisfactory, compact, substantial character that will not "flow" even when wet.

The idea has seemed to be prevalent in the minds of some designers that the slab and buttress dam of this type can be set down anywhere, on the surface of almost any kind of ground. In a pamphlet advertising a dam of this type, it is described as built on "a foundation of quicksand and hay." Without knowing the details, it is difficult to criticize the design, but the writer hardly considers it as conservative engineering. This particular type is advantageous, of course, from the standpoint of economy, when the depth to rock is great, but the foundation material is certain to be wet at times, and a soft rock, hardpan, compact gravel and, in certain cases, a compact clay, would seem to be the foundation range for a dam of this character.

2.—The unit pressure on the bottom of the spread footing should be low and uniform, and the possibility of upward pressure on the footing, or of back-wash undermining it, should be guarded against.

If the slab is inclined at the usual angle of about 45°, uniform pressure at the base of the buttress can be secured by making the base about 1.3 of its height. It is usually assumed that the entire weight of, and pressure on, the slab is transmitted to the foundation through the buttress. A small "wash-wall" at the down-stream edge of the dam prevents undermining of the footing and also confines the foundation material, but, in the writer's opinion, this should not be counted on to resist sliding. Weep-holes are provided in the footing in order to eliminate upward pressure on the base.

3.—The cut-off wall should extend down to impermeable material, below any seams which might communicate between the reservoir floor and the stream bed below the dam.

Practically all the failures of these dams have been due primarily to inadequate cut-off walls. Note especially the Pittsfield, Mass., Dam

* New York City.

† In a letter to *Engineering News*, January 22d, 1914, p. 202.

Mr. Finch.

and the less fortunate Stony River Dam. It is said that engineers should profit by the expensive experience of others, but, unfortunately, some engineers are still willing to "take a chance", usually, however, at the expense of others. It is also far from rare to find cut-off walls built without reinforcement in soft material requiring sheeting and where the sheeting is subsequently pulled. It would assuredly seem that all cut-off walls which are not built in compact earth in an unlined trench, or in a trench in which the sheeting is left in place, should be reinforced.

4.—Stability against sliding must be adequately provided for.

In the letter previously mentioned the writer said:

"A simple calculation shows that in the case of the Stony River Dam a coefficient of friction of about 0.52 is required to prevent sliding. * * * the soil at the dam site [is described] as 'a yellow clay mixed with fine sand or gravel which is underlain by a stiff blue clay, and some seams of a black material occurring in places.' At the best, this material could not be counted on to give a higher coefficient than 0.70 to 0.80 and when wet might give as low as 0.35. Moreover, the design shows weep-holes in the spread flooring, indicating that the designer expected water might, as it doubtless would, occur under the base. Under these conditions it is difficult to see what factor of safety there was against sliding except the shearing value of the concrete of the cut-off wall (which in this design is unreinforced) and the small 4-ft. wash wall at the lower edge of the floor that should most certainly not be counted on as offering any resistance."

Lack of stability against sliding is a well-recognized point of weakness in reinforced concrete structures of the retaining type, and must always receive careful consideration. In retaining walls, it is provided for by projections on the base, and, in the case of a dam of this type, Mr. Scheidenhelm has described the various methods available, and has finally selected the method of utilizing the upper portion of the cut-off wall for this purpose. The writer has been advocating the same method of design in teaching a class in reinforced concrete, and is pleased to see this feature treated so completely and thoroughly in this paper. The slab and buttress dam, properly and conservatively designed, offers economic advantages which undoubtedly make it a most desirable type in certain locations; Mr. Scheidenhelm's paper clears up one of the important points regarding its design, which has long been neglected, and is a most valuable contribution to the literature of the subject. It is indeed unfortunate that the West Virginia Pulp and Paper Company, which, like many other concerns, did not try to economize at the expense of safety, but, on the other hand, insisted from the first on a reliable structure, should have been, through no fault of its own, the victim of such an unnecessary and expensive experience.

Mr. Finch.

One other point in the design of these dams remains to be settled, namely, their architectural treatment. A design for a dam at Coatesville, Pa.,* by Alexander Potter, Assoc. M. Am. Soc. C. E., illustrates the only attempt, so far as the writer is aware, to design one of these structures of really pleasing appearance. In the Stony River Dam, as the author pointed out, no such treatment was considered necessary, but it is more and more evident that, in engineering structures which are near cities or much traveled highways, the appearance must be considered. Too often work of this kind is attempted by a designer who knows nothing of the fundamental principles involved, or it is left to a young architect who is familiar only with house architecture and attempts to apply it to a totally different structure, or applies some inappropriate form of ornamentation that detracts from, rather than enhances, its appearance.

The Engineering Profession lacks in any "tradition", regarding the proper treatment of engineering structures, such as the architect has in the treatment of buildings and on which he is prone to lean, as many believe, too heavily. Many of the engineering works in Europe, which have been held up as examples of good engineering architecture, are merely house architecture applied to engineering work. The true solution of the problem is in developing a suitable treatment, forming, for engineering structures, a tradition based on the same fundamental elements as those on which architecture (building composition) is based, but emphasizing the structural features of the engineering design to a much greater extent than is common in architecture.

The fundamental considerations of unity of effect, balance, proportion, harmony, and climax cannot be taken care of after the structure has been planned and partly designed. They must be kept in mind from the very first and receive their proper consideration in the preliminary schemes, sketches, and plans for the work. The only man who can do this is the engineer himself, who realizes the structural and economic principles involved, and, it is hoped, may soon come to realize the necessity for proper architectural composition as a basis for a final and simple decoration in which the structural features should be emphasized.

Mr. Rutenberg.

P. P. RUTENBERG,† ESQ. (by letter).—European engineers have learned much from their American colleagues, and the war proves the extent to which American methods of solving technical problems, of their organization and realization, have been adopted and developed in Europe. In the special field of dam building they have heard and learned from such world-famous works as the Croton, the Roosevelt, the Elephant Butte Dams, and many others.

* *Engineering News*, February 26th, 1914, p. 461.
† Petrograd, Russia.

Mr. Rutenberg.

If the writer now takes the liberty of criticizing the construction of the Stony River Dam, it is because this structure, in his judgment, is lacking in just that efficiency which is characteristic of American engineering.

Foundations.—As described by the author, the foundation soil at the site of the dam is mainly of a clayey nature, heterogeneous, pervious, and of poor bearing value in general. The examination of the old cut-off wall, and of the buttress footings remaining intact, showed that abundant percolation and leakage existed in the foundation soil of the original dam. "The contact between the original footings and the foundation soil was in some places found to be faulty. * * * Hollow spaces were found under the footings around the 4 by 12-in. weep-holes." In some bays, it was discovered that "the foundation soil had been washed away at the junction between the footings and the cut-off wall. * * * The construction joint would naturally open somewhat, due to the deflection of the foundation soil when loaded. * * * Observations showed that grout under pressure traveled under the footings for a distance of at least 100 ft.", etc. (pages 987-988).

All this was produced by the leakage under pressure during 65 days only, the period in which the original dam functioned, until it failed.

The faulty conditions of the foundation soil were remedied by pressure grouting through the original weep-holes. In this way, the original foundation soil under the footings was more or less compacted, but there surely remained other hollow spaces and pockets from which water under pressure passed, not to the weep-holes of the footings, but in other directions of least resistance, not observed in the reconstruction of the dam. It will be shown later that the author himself admits it, and that his statement (page 988) that "the foundation soil under the original footings was thoroughly compacted so as to warrant the assumption that the footings are everywhere in contact with the foundation soil", is not entirely correct. Percolation and leakage will cause harmful and dangerous uplift pressure in any dam, with any foundation soil, even the best.

The uplift pressure applied to the up-stream part of the base increases the overturning moment of the dam and the unit stresses in the structure and on the soil at the down-stream foot of the dam, where, under the full load of the dam, the values of these stresses are maximum. The uplift pressure on the up-stream part of the base decreases, consequently, the resistance of the dam to overturning, and may render insufficient the resistance of the structure and that of the soil at the base to the efforts of compression and shearing developing there. The same conditions created by the uplift pressure decrease also the resistance of the dam to sliding. This has been

Mr. Rutenberg

the cause of the failure of many dams, even with good foundation soils which have possessed the best frictional resistance.

Therefore, it is impossible to state, as Mr. Scheidenhelm does (page 947), that "the smaller the coefficient of frictional resistance, the less the net effect of the uplift pressure."

Consequently, it is clear that percolation and leakage must be eliminated by all possible means in any dam, in general, and in the Stony River Dam, with its heterogeneous and pervious clay foundations, in particular.

The interception of the leakage and percolation in this dam should have been made directly and immediately on the up-stream face of its cut-off wall and discharged down stream by special channels without any pressure.

Now, the principles on which the Stony River Dam was reconstructed are quite different. On page 997 we read:

"It was believed to be preferable, therefore, to take such risk as might result from the existence of pockets, as it were, of unrelieved uplift pressure near the down-stream side of the cut-off wall rather than to invite further leakage by tapping such relatively harmless, deep-lying pockets of water under pressure."

This statement, it seems to the writer, does not tally with the most vital principles in dam-building, namely, that water under pressure in the foundation soil is never harmless.

According to the foregoing consideration, the system of drainage adopted for the Stony River Dam consists of 3-in. wrought-iron pipes, perforated with four ⅜-in. holes per linear foot, one hole in each quadrant; three pipes per bay, driven into the foundation soil vertically, the first "about 20 ft. down stream from the cut-off wall, except at the bays of lesser height, where they are at a minimum distance of 12 ft. from it."

The writer believes that:

1.—A 3-in. pipe with four small perforations per linear foot for a bay 15 ft. high is useless for drainage, even if the drainage pipes described by the author function perfectly well.

2.—The small perforations in the pipes must undoubtedly have been clogged with clay in the process of being sunk. Mr. Scheidenhelm states (page 998) that "any considerable hydrostatic pressure near the drain pipes would soon open the perforations." He admits the presence in the foundation soil of considerable hydrostatic pressures at a distance of 20 ft. from the down-stream side of the cut-off wall, which is about the middle of the base. Consequently, by the improper location of the drainage pipes, alone, the up-stream half of the base is exposed to dangerous uplift pressures, with all previously stated consequences, *viz.*, decrease of resistance by overturning, increase of

Mr. Rutenberg.

the unit stresses in the structure and on the foundation soil, saturation of the clay foundation soil with water, and decrease of its resistance to sliding; which, as the writer understands, cannot but be harmful, and all this solely because the drainage pipes, even assuming that otherwise they function perfectly well, are not in the proper places.

3.—Some of the drainage pipes have been driven vertically to a depth of 20 ft. into the foundation soil. When they are filled with drained water, it is clear that their lower perforations are submitted to the pressure of a column about 20 ft. high, and at this lower stratum of the foundation soil the leakage will not be able to penetrate into the drainage pipes, unless it is of greater hydrostatic pressure. Only a small part of the leakage will penetrate through the small perforations; the remainder will continue its way down stream into the foundation soil, where the resistance is weaker. Besides, there is a possibility that the drainage pipes will be filled through the higher perforations from the higher strata of the foundation soil, and that the collected water will be conducted through the pipes and their lower perforations, by the water pressure thus formed, into the otherwise dry lower strata of the foundation soil.

In fact, on page 1000, the author takes cognizance of such phenomena, for which manifestation he "has been unable to advance any explanation which is satisfactory to himself."

The writer, therefore, considers these pipes, not as a drainage system, but rather as a means of introducing water into the foundation soil, and not only useless, but dangerous to the safety of the dam.

Resistance to Sliding.—On page 908, we read:

"The method adopted [for increasing the resistance to sliding] is believed to be new, and consists in the use of anchoring walls extending to a considerable depth into the underlying foundation soil, and, in effect, utilizing the weight of that underlying soil as well as the resistance (to horizontal movement) of the soil immediately down stream from the structure."

These anchoring walls are two: one at the heel, and another at the toe, of the original structure which remained intact.

To render the above-mentioned service, the heel-wall must be strong enough to be able, in case of a down-stream sliding of the dam, to function as a cantilever which can overcome the resistance of the underlying foundation soil to sliding and shearing.

The paper does not give the dimensions and calculations of the anchoring walls, but, from Plate XII, it is clear that they are too weak to serve this purpose. The heel-wall is not able to compact the underlying foundation soil, and, therefore, make it less pervious by any down-stream movement on the part of the dam, as the author believes. It will simply be broken in this case, opening the joint

between the upper structure and the cut-off wall, as happened in the original structure, according to the description on page 959. Mr. Rutenberg.

The toe-wall, as constructed, will aid in collecting the leakage under the dam. Consequently, it will increase the uplift pressures and the quantity of water in the foundation clay, decreasing the resistance of the dam to overturning and sliding.

Openings should have been made in the vertical part of this wall, directly under the footing floor of the dam to provide a free exit for the leakage.

As far as the two anchoring walls are concerned, the writer does not agree with the author's assertion that "the reconstructed dam acts essentially as a monolith" and, consequently, he does not agree that "the horizontal member of the toe-wall in effect increases the width of the base of the dam, thus decreasing the unit vertical load on the foundation soil." (Page 960.) The efforts transmitted by the buttresses to the foundation soil have their maximum value at this point, and, the writer believes, under the existing circumstances, will rather break this horizontal member of the toe-wall.

The under-cut slope of the heel-wall presents, besides, a surface for the application of uplift pressures, which, with their big moment arm, decrease also the stability of the original structure against overturning.

In the reconstruction of the intact part of the dam, the only things to do were: to fill, if possible, all the holes found in the foundation soil; to repair the cut-off wall, and to build a reinforced concrete wall up stream from the old cut-off wall, bearing upon this by concrete apertures, in order to form chambers which would be able to maintain the percolation through this drainage wall and conduct it without pressure down stream from the dam by convenient channels.

The two anchoring walls with the drainage pipes have weakened the original stability of the dam.

The "new theory" of resistance to sliding, with the investigation about the "plane of least resistance", with the tests, calculations, and deductions of an "average" coefficient of frictional resistance of 0.61 in wet clay, is an interesting theoretical exercise, but without practical value for the reconstructed dam. One is the frictional resistance of a cubic foot of clay, pulled by two men under the conditions of the improvised laboratory described; the other is the effective frictional resistance of the wet clay of heterogeneous structure in the real foundation soil loaded by a head of 90 ft. and more, or by about 6 000 lb. per sq. ft.

There are dams in which the necessary weight is obtained by clay, sand, pebbles, even water, included in a reinforced coffer, the bottom of which constitutes an elastic monolith with other coffers.

Mr. Rutenberg.

If percolation took place, it would be applied to the bottom and, consequently, to the whole structure of the dam. The material of light weight cannot be washed from them.

In the Stony River Dam, however, engineers cannot seriously consider for its resistance to overturning and sliding, the "weight" of the underlying foundation soil, which can be and is, as is known, washed away by the existing leakage and percolation.

Spillway.—Not being acquainted with the hydrological conditions of America, the writer cannot give an opinion as to whether the spillway capacity provided in the reconstructed dam is adequate or excessive; but one thing is clear: that by adding 3½ ft. of water to the original level in the reservoir, the horizontal water pressure and its overturning moment are increased by about 20% for the typical section indicated on Plate XII. The increase is greater for the sections of less height.

The parapet-like addition to the original structure and the curtain-wall and roof, contribute a vertical effort of important value, which passes into the down-stream third of the base. Both conditions increase the overturning moment, consequently, they also decrease the safety of the original structure. The upper structure in the new spillway is made heavier than in the original dam.

For each horizontal section the water loading is exactly the same in the new and in the old structure. Thus, either the original structure is insufficient or the excess of the new is useless. In any case, the subjection of the original structure to greater loadings and unit stresses than those for which they were evidently designed is dangerous; 22 000 lb. per sq. in. = 15.5 kg. per sq. mm. in the steel, and 800 lb. per sq. in. = 56.5 kg. per sq. cm. in the concrete, are too much, at least, according to European provisions. The paper does not give the necessary data with which it would be possible to compute the unit stresses in the structure and on the soil, but the writer is sure that the load on the soil at the down-stream foot of the dam is excessive. Since, under favorable circumstances, a part of the original structure remained intact, it was advisable to maintain the original maximum water level.

The allowed over-topping of 2½ ft. of water from a height of 40 ft. between Buttresses 19 and *A* is, it would seem, also dangerous. The shock of the falling water will not only break the provided horizontal and inclined reinforced mat, but, when that occurs, it will wash the soil from under the dam footings.

On page 917, Mr. Scheidenhelm, criticizing the rupture of the original dam, says: "The conditions obtaining at the Stony River dam site are such that a safe dam could be built there. * * * The dam

should, and could, have been designed and constructed so as to be absolutely safe." Mr. Rutenberg.

The writer believes the reconstructed dam is less safe than the original structure.

The flaws in the foundation soil which had not been taken care of by the constructors of the original dam, widened and became more pronounced by the water pressure formed by the old dam. After the rupture occurred, some of these flaws came to light and could not but be remedied; so that the foundation soil was relatively reinforced, thus giving it another short lease of life, longer than for the original dam.

The writer is firmly convinced, however, that were the reservoir now to be emptied and the foundation soil examined it would be found to be in a very bad state.

"Certain of the drainage openings yielded muddy water, instead of the normally clear water. * * * Such openings were grouted shut, rather than take any chances of harmful erosion under the footings." (Page 1000.)

This "harmful erosion" has surely found other ways, unobserved by the author.

The writer is firmly convinced that the reconstructed dam will also be broken, perhaps soon, if adequate repairs are not made in time. It is a question of preventing a new disaster. These are the writer's reasons for taking the liberty of criticizing the work done in the reconstruction of the Stony River Dam.

FRED F. MOORE,* M. AM. SOC. C. E. (by letter).—After study of this excellent description of the interesting reconstruction of an uncommon type of dam, two impressions stand out prominently: Mr. Moore.

First, that there is a dearth of information regarding sub-surface conditions as a guide to the original designs. Even now, comprehensive knowledge of the character of the foundation materials, and the behavior of these materials under the conditions imposed, does not appear to be sufficient to justify the conclusions reached by the author as to the margins of security of the reconstructed dam. Tests of frictional resistances of soils, as carried out in connection with this work, are of doubtful value as an aid to the judgment, because of the small areas in contact, and the values of frictional resistance adopted for the design seem to be considerably larger than even the indications of these experiments would justify.

Second, with reference to the function of the walls at "heel" and "toe" in resisting movement of the structure as a whole, the analyses which consider sliding and overturning independently would appear to befog rather than to aid the judgment. Materials such as these,

* New York City.

Mr. Moore. mixed with clay and saturated with water, perhaps under considerable pressure, and subjected to large loads, would flow, or, at least, transmit pressures in all directions like a liquid. In order that the cut-off wall at the "heel" may aid in resisting sliding as described, there must be a sensible movement of the structure as a whole, with consequent large uplift on the base of the dam. Hence, the sliding and overturning, or, perhaps better, the floating, of the structure must be considered with reference to the effect or reaction of these tendencies one on the other. That is, the materials under the dam, with reference to the function of the cut-off wall in resisting sliding, must be considered as a flowing medium rather than one in which a sliding may occur on certain planes like one solid on another.

The wall at the "heel" does not appear to have sufficient strength for the purpose contemplated. If this wall is fractured, water under reservoir pressure in considerable quantity would have access to the materials under the dam. The drainage provisions appear to be a doubtful reliance for minimizing uplift pressure. The danger of portions of the dam being floated off the foundations from leakage of water under pressure through the cut-off at the "heel", and through, or under, the cut-off at the "toe", at a time of large overflow, appears not to have had sufficient consideration. Although the idea of using the materials between the cut-offs and immediately down stream from the "toe" to resist sliding is a good one, it is doubtful if the reconstructed dam has a sufficient margin of security to warrant a conclusion that it is not likely to fail again.

The run-off assumed for the design of the spillway appears to be reasonable for the purpose, but the margin of 6 in. against overtopping is too small. A flow of 2 ft. of water over the intermediate spillway would not fall "well-nigh" vertically. Such a flow would strike the slope of the fill (Plate XII), which is inadequately protected for such a condition. Even water falling into the concrete channel from the top of the dam would start serious trouble through erosion of the bank by wash. Regardless of damage by falling water, the concrete channel is too small. Any considerable flow over the intermediate spillway would be almost certain to start cutting of the materials at the "toe".

The use of brittle steel pins for the flash-board support is unusual, and would seem to be an expedient of doubtful value.

Mr. Downs. W. S. Downs,* Esq. (by letter).—Ignorance of the coefficient of sliding friction between rock sub-strata, and the resulting neglect to provide the proper safeguards, have been the cause of numerous dam failures. Such failures never occur where the rock is of igneous origin, such as granite, trap, or the like, but authenticated records

* Morgantown, W. Va.

show that this danger lies in the softer sedimentary formations where the rock is horizontally stratified or nearly so. Mr. Downs.

Probably in no extensive geological formation is sliding or slipping of materials more in evidence than in the formations of the Carboniferous period, especially that portion of these formations which include the coal measures of the Appalachian fields and in which the Stony River Dam is situated.

These formations are highly stratified, the strata usually consisting of rather soft shales, ranging from a very soft fire-clay shale to a sandy shale, with occasional thin strata of coal and limestone and lentils of sandstone. One of the chief difficulties in studying the formations, however, is the non-uniformity and non-persistency in the character of the strata. The same stratum sometimes varies from a hard sandy shale to a soft fire-clay shale within a few hundred feet. The shales decompose and disintegrate very rapidly when exposed to atmospheric conditions, and, when decomposed, the resulting clays and soils are difficult to drain and exceedingly unstable.

The available data on the coefficient of static friction, especially as to layers of shales and clays, are extremely meager. In fact, very little has been learned on this subject since Morin made his experiments in 1834. The intensity of the pressure and the length of the time of contact between the two surfaces are factors the influence of which on the universal laws of friction are but vaguely understood. Therefore, until more extensive experiments have been made, and these general laws are more thoroughly understood, it behooves the engineer not only to make as thorough tests as practicable on the materials in question, but to use an ample factor of safety in designing.

Unfortunately, tests on a large scale are practically impossible, and engineers must often base their conclusions on tests of small areas of contact and with relatively light pressures. In applying these tests to the whole foundation area, they must depend largely on their knowledge of the geological conditions, coupled with an abundance of good judgment.

Mr. Scheidenhelm's tests on the frictional resistance of the foundation soils, as shown in Table 2, are interesting, and are valuable as an indication of the character of the materials in question. However, too much dependence should not be placed on the results of these tests. The same materials might show very different results when subjected to the more intense pressure of the dam for an indefinite length of time; and, moreover, the condition of saturation, as it must exist beneath the dam, might change the value of the coefficient of friction very materially. The writer has had occasion to study numerous slips and landslides in materials of this character, and has been surprised to note the vast difference in frictional resistance

Mr. Downs. between dry and wet clays. He has in mind one instance where dry clay soil indicated a coefficient of frictional resistance of more than 0.7, but after it had become thoroughly saturated for a considerable time, the coefficient of frictional resistance was less than 0.2.

Referring to the results of Mr. Scheidenhelm's tests, in Table 2, it will be observed that there is considerable difference in the frictional resistance between wet and moist samples of the same materials, and therefore the question arises: Might not the frictional resistance be still lower than is indicated by the tests when the clays are subjected to the conditions that will exist in the foundation materials of the dam?

At first thought, the coefficients of frictional resistance for shales (0.40 and 0.50), assumed by Mr. Scheidenhelm in the design for the reconstruction of the dam, may seem to be rather low. However, it should be remembered that the shales in question have "pronounced horizontal laminations" and are somewhat disintegrated, and that clay seams exist in places.

The lamination planes in the fire-clay shales of the coal measures often show a slick, smooth surface, sometimes of a more or less slippery nature. It is very evident that the cohesion between the substrata at these planes must be exceedingly slight, and, unless the planes of contact are very much warped or of limited extent, the resistance of the materials to sliding must be rather low.

Mr. Coburn. H. L. COBURN,* M. AM. SOC. C. E. (by letter).—The Engineering Profession is to be congratulated that there are engineers who have the time, the disposition, and, more especially, the ability, to prepare such a paper as this. One rarely sees a more complete exposition of an engineering problem from inception to finish than is here presented. The writer says from inception, for, to all practical purposes, this was an entirely new problem, as few or no data were available for the author's use.

As originally built the Stony River Dam was designed to meet certain stated conditions of foundation, which, subsequent events proved, did not apply, and the failure of the dam is attributable to this fact alone and not in any way to the type of structure. No dam designed to fulfill the conditions given could have withstood the treatment to which this one was subjected, and the writer thinks it an evidence of sound fundamental principle that the dam failed only in part and that part so gradually.

This is neither the time nor the place to discuss the conditions that led to the designing and building of this dam on data that were wholly inadequate and erroneous. The great lesson to be learned from the failure is the advisability, not to say necessity, of complete preliminary investigations on which to base design, and adequate and

* New York City.

competent engineering supervision of construction—money thus spent is "well spent." Mr. Coburn.

As to the reconstruction, though the writer doubts that all the safeguards against a possible second failure, which Mr. Scheidenhelm has taken, were necessary, yet he feels that, in the circumstances, they may be justified. If more accurate data were available as to "passive thrust" or resisting power of the local soils, and more real information as to coefficient of friction between these soils and the concrete cast thereon, engineers might criticize his details in some respects, but with the limited knowledge of actual values, and particularly in view of the fact that this was a case of rebuilding a structure which had partly failed, and about which very sensational stories had been circulated, the writer considers that if the dam was to be rebuilt at all, it was good judgment to assume the "worst possible conditions" and to make assurance doubly sure.

H. F. DUNHAM,* M. AM. SOC. C. E. (by letter).—In the discussion of a paper on the repairs made to a structure, it may not be in order to refer to the reasons for erecting that structure; but, if such reference is allowable, replies to two or three questions may be of interest. Mr. Dunham.

An article published in a technical journal† at about the date of the construction of the Stony River Dam contained a few words relating to the object to be secured by the improvement. At some point on the North Branch of the Potomac below its Stony River tributary there was a paper mill with an insufficient supply of wash-water in dry-weather periods. There was no mention of the use of an increased flow of the river for power purposes. There were no figures for the dry-weather discharge of the main stream at the mill, nor of its tributary. The additional quantity of wash-water needed was not given, and, furthermore, there was no longitudinal profile of either the North Branch or the Stony River, and no description of the river valleys or reference to any other method of providing the unestimated but desired supply.

It should be generally admitted that if, within a few years, the supply of wash-water has approached the desired quantity there would certainly be enough at all times, if the natural or original conditions pertaining to those streams could be restored. When the entire district was heavily wooded, the winter snows were longer in melting, the ground did not freeze to such depth as now, and more of the spring rainfall remained as ground-water for a longer period. Moreover, when floods were less frequent, fallen tree trunks and branches lodged in narrow channels, holding the water back. The beaver built his dams, with similar results, and when they were old he, too, repaired

* New York City.

† *Engineering News.*

Mr. Dunham.

them. All of this was favorable to a longer and more uniform flow of water in dry-weather periods than obtains at the present time. It may be within reason to inquire how far Nature's regulation of flow in such streams can now be imitated. The forest and frost are items that cannot be changed, but, given favorable topography and soil, the fallen timber dams and those made by the beaver with the higher ground-water table could be copied successfully and possibly improved.

The photographs in the paper, and the dam itself, 1 000 ft. long at the most favorable location, indicate a valley of some width. The sandstone mentioned, and the fact that the water found its way under the cut-off wall, show the existence of a somewhat porous soil. It is evident that the structure described was expensive. Had a part of that expense been used to construct a number of low but permanent dams at favorable places for low dams, each to be provided with a cheap low-water sluice-gate that would require a minimum of attention, a considerable change in the dry-weather flow of the stream would have been secured. The author refers to the existence of ground-water in and about the foundations of the dam. To raise the level of such ground-water over considerable areas gives available storage, and water thus stored is not subject to such rapid evaporation as surface water.

The dams, of course, would hold back surface water as well as ground-water. The extent to which the flow of a stream is regulated by higher ground-water level is often surprising. This is well illustrated by rivers flowing through wide flood-plains which, sponge-like, retain large quantities of flood water which are gradually returned to the river in its lower stages.

At certain seasons, especially in the spring, streams of moderate or sluggish current may carry too much silt to be suitable for a supply of wash-water. In the article previously referred to no mention was made of any filtration process, but, if that method is used, a reservoir below the mills suitable for the purpose of sedimentation and refiltration should have substantial value.

The writer has no wish to "go behind the returns" or to ask for any reference to the business affairs of business men that need not be disclosed. The first studies pertaining to any improvement are always interesting, and they are quite apt to be overlooked in the description of a finished work.

How the cost of the dam as it is now compares with the estimated cost of a gravity-section dam of the same general dimensions would be of interest, as would also the question of a curved versus a straight dam for structures of either type in that place.

ORRIN L. BRODIE,* M. AM. SOC. C. E. (by letter).—The author is to be thanked for the lucid and well-arranged presentation of the subject matter relating to the reconstruction of the Stony River Dam, and the thorough manner in which he has treated the various phases of that work. Mr. Brodie.

One of the most striking features of his design, to the writer at least, was the unique method of anchoring the up-stream heel and cut-off. Relative to this matter, certain statements of the author in his brief outline of the previous failure of the structure were impressive. These were:

"Failure occurred where the up-stream cut-off wall extended only a short depth (5 to 7 ft.) into the over-burden."

"Failure was caused by undermining due to leakage."

"The type of dam was not in any way a cause of failure."

Thoughtful consideration of these three statements taken together forces on the writer the following query:

Would not a dam subject to considerable head of water, such as the one described, but containing sufficient mass that could contribute by its dead weight a resistance *per se* to sliding and overturning tendencies, be more satisfactory in every respect than one of the type here considered? Even though the hollow concrete type, such as the one described in the paper, may possess decided advantages in the matter of stability against overturning, there is always the possibility of the admission of water below it, which, besides increasing its tendency to slide, destroys any advantage inherent in its form in the matter of stability. Besides, as shown by the author, an up-stream cut-off thoroughly anchored to the heel seems to be a vital necessity. It is also significant that the reconstruction involved a quantity of masonry equal to that of the initial construction, which might better have been utilized in the first place.

The method of computing the storage effect of the reservoir area with respect to the spillway run-off was interesting to the writer, as was the detail of the spillway shape, as depicted on Plate X and noted by the author as being a more advantageous crest than that of the old spillway.

An investigation as to spillway run-off with respect to two basins, the waste weirs of which were at different crest elevations, was made by the writer, and involved an interconnecting tunnel between these two reservoirs (constituting the substitute supply works, connected with the new Kensico Reservoir for New York City).

The understanding of the method will be facilitated by the following nomenclature:

* New York City.

Mr. Brodie.

Volumes are in cubic feet; flows in cubic feet per second; and times, in seconds.

H_1', H_2', and H_1'', H_2'', are elevations of water surfaces in the respective reservoirs, Nos. 1 and 2;

t = time for Reservoir No. 1 to rise through a small distance (H' to H'');

V_1 = increment of capacity due to ($H_1'' - H_1'$) for Reservoir No. 1;

V_2 = increment of capacity due to ($H_2'' - H_2'$) for Reservoir No. 2;

I_1 = average inflow during time, t, from water-shed of Reservoir No. 1;

I_2 = average inflow during time, t, from water-shed of Reservoir No. 2;

i = average flow, during time, t, through tunnel and from Reservoir No. 1 to Reservoir No. 2;

Q_1' and Q_2' = flow over respective weirs at the beginning of time, t; and

Q_1'' and Q_2'' = flow over respective weirs at the end of time, t.

For Reservoir No. 1:

$$t = \frac{V_1}{I_1 - i - \frac{1}{2}(Q_1' + Q_1'')} \quad \ldots\ldots(1)$$

For Reservoir No. 2:

$$t = \frac{V_2}{I_2 + i - \frac{1}{2}(Q_2' + Q_2'')} \quad \ldots\ldots(2)$$

Eliminating i between Equations (1) and (2):

from Equation (1) $$t\left[I_1 - i - \frac{1}{2}(Q_1' + Q_1'')\right] = V_1 \quad \ldots\ldots(3)$$

from Equation (2) $$t\left[I_2 + i - \frac{1}{2}(Q_2' + Q_2'')\right] = V_2 \quad \ldots\ldots(4)$$

from Equations (3) and (4)

$$t = \frac{V_1 + V_2}{I_1 + I_2 - \frac{1}{2}(Q_1' + Q_1'' + Q_2' + Q_2'')} \quad \ldots\ldots(5)$$

Method, by successive approximations, of applying the foregoing expressions:

V_1 is a direct function of t and i, that is, $V_1 = f(t, i)$ and must be so considered.

Mr. Brodie.

Begin with Equation (5): First, assume values for V_1 and V_2 and corresponding values for the other terms in the right-hand member. Substitute the value of t thus found in the left-hand members of Equations (3) and (4), with the corresponding new value of i, until Equations (1) and (2) are satisfied. The second value of t can thus be tested by Equations (1) and (2). The values of V_1 and V_2 of Equations (3) and (4), respectively, must agree with the values of V_1 and V_2 in Equation (5).

The calculations, as briefly outlined in the foregoing, may be made in connection with the use of chosen run-off diagrams, together with capacity curves prepared both for the weirs, tunnel, and reservoirs. The results may be shown by appropriate curves of reservoir rise with time intervals from the beginning of the storm, or with respect to any stage desired.

In connection with the consideration of the spillway shape, the writer has determined the applicability of a parabola, the origin of which may be taken at the actual crest of the weir and the parameter at about 1.8 times the head of full reservoir level on the so-called "theoretical crest" (that is, the actual crest of a corresponding thin-edged weir). This parabola, with axis vertical and through the crest, will determine approximately the lower nappe or sheet of overfall for a weir.

The study leading to this conclusion was based on weir experiments by M. Bazin. This parameter may be increased for practical considerations to as much as $2\frac{1}{2}$ times the head.

The writer is not aware of the detailed method by which the shape of the new spillway crest of the Stony River Dam was fixed, but, by the foregoing method, he calculated the crest for the given head and was interested to find that, as far as could be ascertained by careful scaling of the spillway of Plate X, a practical identity resulted. The advantage of a larger value than 1.8 for the parameter factor used by the writer in this instance is that it permits of flattening the curve just down stream from the crest, thus improving the flow conditions. For a solid masonry weir, a larger parameter enables the parabolic section to be extended to a lower elevation than otherwise. In the case under consideration it was obvious that the comparatively steep apron slope required a minimum value for this particular parameter.

The author intimates that the preliminary soundings were made by test pits and auger borings, that failure occurred where the upstream cut-off wall extended only from 5 to 7 ft. into the over-burden, and that the technical advisers consulted on the original project were not familiar with the local conditions. Later, it appears, the results of core borings driven for reconstruction investigations disclosed

Mr. Brodie.

lentils and alternations of pervious with impervious strata, and that sandstone boulders or false cliffs had been mistaken for bed-rock beneath the original cut-off construction.

These facts cannot emphasize too strongly the great importance of extensive sub-surface investigation preliminary to construction such as this, and the author's words in regard to foundation conditions as uncovered in the subsequent explorations, that they "required the most serious consideration and care", are conclusive.

Mr. Cain.

WILLIAM CAIN,* M. AM. SOC. C. E. (by letter).—The writer is especially interested in the author's use of "anchoring walls" to increase the margin of security against the sliding of the dam. Such walls, projecting below the foundation, have been used repeatedly in dam and retaining wall design, but the projections were generally of small depth, so that little attempt has been made to state the principles affecting their design. The author's distinct contribution consists in the use of anchoring walls of such depth that the weight of the soil, from the foundation to the level of the lower end of the anchoring wall, is quite appreciable, and is utilized in increasing the resistance of the dam to sliding by lowering the possible plane of sliding from the foundation level to one passing through the bottom of the anchoring wall. He has entered into great detail regarding the principles affecting this design, and, in connection with it, has discussed the passive resistance of earth placed below the dam to sliding up a possible plane of rupture.

It is to be regretted that the author, in his experiments to determine the combined "adhesion" and friction of the various soils, did not apply increasing weights to the box containing the soil, and likewise measure the pull for each weight in turn, corresponding to "impending motion"; meaning by that term, that no actual sliding occurs, but that any increase in the pull, however small, would cause actual motion. If this had been done, the actual values of the coefficients of friction and cohesion could have been ascertained and used in the analysis. As the pulls were only recorded when the box containing the clay was in actual motion, the results give neither the friction coefficient alone nor the combined full cohesion and friction, such as would be actually exerted near the foundation of a stable dam, or perhaps on some lower plane or curved surface.

The results refer only to a combined friction and cohesion ("adhesion", as the author characterizes it, for this case), when the box was in motion. The numerical values of the "coefficients" in Table 2 are so much larger than the coefficients of friction of various clays, as given by Bell, as quoted in Table 7, that evidently a very appreciable amount of cohesion ("adhesion") was exerted during the motion. This

* Chapel Hill, N. C.

negatives the idea, suggested by the writer in a previous paper, that, after motion began, possibly all cohesion was destroyed, so that only friction remained to resist the pull. Evidently, from the results, although a large part of the full cohesion of the solid clay was not exerted during the motion, still an appreciable part of cohesion in addition to the friction was exerted during the actual sliding of clay on clay. Mr. Cain.

Coulomb's laws, concerning "impending" sliding of earth on earth, are symbolized in the equation:

$$Q = f\,P_n + c\,A \qquad (1)$$

where Q = the total resistance to sliding in the plane of shear, in pounds;

f = the coefficient of friction;

c = the cohesion in the plane of shear, in pounds per square foot;

P_n = the normal pressure in the plane of shear, in pounds;

A = the area, in square feet, of the plane where shear is impending.

Also, if ϕ = the angle of friction, then $f = \tan.\ \phi$.

Table 7 gives experimental values of f, ϕ, and c, quoted from the writer's paper on "Cohesion in Earth"*, the first five values being from Bell, the last two from Jacquinot and Frontard.

TABLE 7.

Character of earth.	$f = \tan.\ \phi$, coefficient of friction.	ϕ	c, coefficient of cohesion, in pounds per square foot.
Very soft puddle clay, virgin state	0.000	0°	450
Soft puddle clay, virgin state	0.052	3°	670
Moderately firm clay, virgin state	0.087	5°	1 120
Stiff clay, virgin state	0.123	7°	1 570
Very stiff boulder clay, virgin state	0.287	16°	3 580
Sand-clay, very humid, kneaded	0.145	8°15′	385
Sand-clay, damp, virgin state	0.187	10°35′	443

The sand-clay referred to in Table 7 was taken from a well-rolled dam, made of the best materials, its composition being 60% clay, 32% silica as an impalpable dust, and 8% silicious sand.

Mr. Scheidenhelm's Table 4 furnishes the figures given in Table 8. Since, in the author's experiments on the direct shearing of clay, the normal pressure, P_n, on the initial area was zero, it is seen, from Equation (1), that the last two columns give the coefficient of cohesion, c, in pounds per square inch and pounds per square foot, respectively.

* *Transactions*, Am. Soc. C. E., Vol. LXXX, 1916, pp. 1322, 1333.

Mr. Cain.

TABLE 8.

Character of soil.	Shearing value, in pounds per square inch of initial areas.	c, coefficient of cohesion, in pounds per square foot.
White clay	12.1	1 742
" "	26.6	3 830
" "	20.7	2 981
" "	26.0	3 744
" "	22.8	3 283
Black gumbo	9.6	1 382
" "	16.1	2 318
Black loam	16.0	2 304
Sandy yellow clay	4.6	662
" " "	2.7	389
Average	15.7	2 260

It is seen, also, that the values of c compare very well with some of those in Table 7. Possibly, if the values of ϕ had been determined from appropriate experiments, they would also have compared favorably with the previous determinations.

It is important to observe that the time element affects all results very appreciably. Thus, Collin, in 1846, found that the resistance to shear in clay produced in from 12 to 15 min. was only one-third or one-fourth of that produced in from 12 to 15 sec. Bell states that all his tests were of considerable duration. This matter needs special attention by experimenters. As the author states that "the effect of the length of time of application of a given shearing load was not investigated," it is probable that the values of c, as given in Table 8, are all too large.

If certain values are assumed for ϕ, from Bell's experiments on clays as roughly applicable to the author's experiments relating to the resistance of clay on clay when in motion, a rude surmise may be made of the corresponding value of c for cohesion of motion.

Thus, for "white clay, fine-grained, wet", assume $\phi = 6°$; then, from Table 2, let $P_n = 200$ lb. and $Q = 0.34\ P_n = 68$ lb. With regard to A, the author says, "ordinarily, more than $\frac{1}{3}$ sq. ft. of the material under test was actually in contact." As definite information is lacking, it can only be assumed that $A = \frac{1}{3}$ sq. ft.; hence, by Equation (1),

$$68 = 200 \text{ tan. } \phi + \frac{1}{3} c,$$

or, for $\phi = 6°$, assumed, tan. $\phi = 0.105$. Therefore, $c = 141$ lb. per sq. ft. For the same "white clay, moist", from Table 2, if $P_n = 200$ lb., as an average, $Q = 0.42\ P_n = 84$ lb. Therefore, for $\phi = 6°$ (as before) and $A = \frac{1}{3}$ sq. ft., by Equation (1), it is found that $c = 190$ lb. per sq. ft.

Mr. Cain.

Again, for "yellow clay containing some grit, fairly wet", assume $\phi = 12°$ (tan. $\phi = 0.213$), $P_n = 200$ lb. Therefore, by Table 2, as an average, $Q = 0.68\ P_n = 136$. Taking $A = \frac{1}{3}$ sq. ft., by Equation (1), $c = 280$ lb. per sq. ft. Although the values of A and ϕ assumed are doubtless incorrect, the roughly approximate values of c, as computed, are instructive as showing a very appreciable cohesion, even when the upper layer of clay is in motion.

The author gives, on page 958, for certain conditions pertaining to the original dam before failure, the horizontal water pressure = 1 013 600 lb.; weight of dam and water over it = 2 030 400 lb.; both for a 15-ft. bay. If the base is 52 ft. wide, $A = 52 \times 15 = 780$ sq. ft.

Consequently, assuming the low value, $c = 660$ lb. per sq. ft. (say, for the yellow clay) and $\phi = 12°$ (tan. $\phi = 0.213$), on substituting in Equation (1), we find,

$$Q = 2\,030\,400 \times 0.213 + 780 \times 660 = 947\,300 \text{ lb.},$$

which is but little below the water pressure tending to cause sliding. In fact, the resistance to sliding is exactly equal to the water pressure for $\phi = 13°\ 50'$, which is a possible value.

This computation involves the assumption that there exists a cohesion between the concrete and clay at the foundation of 660 lb. per sq. ft., and the fact that the dam stood renders the assumption probable. No illustration can be given that more forcibly points to the need of "comprehensive experimentation" to determine the coefficients of cohesion and friction, not only for earth on earth, but likewise for concrete or other masonry on earth; for here is a dam that stood, which presumably should have failed if no cohesion was exerted at the base. This supposed cohesion that engineers (the writer included) have hitherto ignored, in computations affecting the sliding of dams and retaining walls, is probably a vital element concerning stability, and it doubtless has saved many walls from destruction by furnishing an additional resistance to sliding over that due to friction alone.

The argument that the resistance to sliding can be computed in terms of a friction coefficient alone, supposed to allow for the combined cohesion and true friction, is untenable, as the writer has conclusively shown.* The error can likewise be realized by a numerical example. Thus, on dividing Equation (1) by A, and putting $q = \frac{Q}{A}$ = unit total resistance to sliding, and $p_n = \frac{P_n}{A}$ = unit normal pressure, we have,

$$q = f\,p_n + c \qquad (2)$$

From Table 8, the lowest value of c, for the "sandy yellow clay" is

* "Cohesion in Earth", *Transactions*, Am. Soc. C. E., Vol. LXXX, pp. 1332–1334.

Mr. Cain. 389, say 400, lb. per sq. ft. On arbitrarily assuming $\phi = 12°$ or $f = \tan. \phi = 0.213$, Equation (2) reduces to,

$$q = 0.213\ p_n + 400.$$

Now, if it is assumed that a friction coefficient, $f = \frac{1}{3}$, with $c = 0$, can sufficiently represent the value of q, which denote by q', we have, from Equation (2),

$$q' = \frac{1}{3}\ p_n.$$

It will be found, for $p_n = 3\,333$ lb. per sq. ft., that $q = q'$; but, for $p_n < 3\,333$, $q' < q$; whereas for $p_n > 3\,333$, $q' > q$.

Thus, for $p_n = 1\,000$ lb. per sq. ft., $q' = 333$, $q = 613$ lb. per sq. ft.; but when $p_n = 6\,000$ lb. per sq. ft., then $q' = 2\,000$ and $q = 1\,678$ lb. per sq. ft.

The differences would be much more marked had large values of c been taken, corresponding to the "white clay" or "gumbo." As to the value $\phi = 12°$, arbitrarily assumed, it seems probable, from the experimental values of Bell, given in Table 7, that ϕ lies somewhere between 7° and 16°, and thus an average was taken as a probable value. Likewise, from the author's Table 2, the yellow clay shows a high, comparative value of the "coefficient of frictional resistance", including "adhesion", so that, possibly, ϕ should lie nearer to 16° than 7°, and 12° is possibly a little below the true value.

In connection with the foregoing values of p_n, it is of interest to know that, ignoring the cut-off wall and taking the area of the base of the dam as 52×15 sq. ft. for one 15-ft. bay, the average unit pressure on the foundation of the old dam is $\frac{2\,030\,400}{52 \times 15} = 2\,600$ lb. per sq. ft.; also, if the earth below it weighs 100 lb. per cu. ft., the unit pressure at 15 ft. below the foundation (at the bottom of the "anchoring wall", or at the level, $A\ B$, of Plate XII), amounts to 4 100 lb. per sq. ft. The values of q and q', as found from the foregoing equations, do not differ greatly for these values, 2 600 and 4 100 for p_n, but this is only due to the particular values of f and ϕ assumed.

It is not pretended that these are near the true values, as the computation was simply made to show what differences might occur by the two methods of estimating the resistance to sliding, and that the value of p_n, at the foundation or below it, is an important factor in the computation.

Although the data as to c and ϕ are "not sufficient in number and reliability" to lead to an exact determination of the passive resistance to sliding of this dam, by the theory of coherent earth, nevertheless, some interesting conclusions can be drawn, by finding, by this theory,

probable values of c and ϕ, necessary to the stability of the dam for each case of loading given by the author on pages 956-957. Mr. Cain.

It is very possible, as new experimental determinations come in, that surprises as to the true laws affecting friction and cohesion await us in the future, but, as far as the experiments go, Coulomb's two laws have been verified, and they will be made the basis of the following computations.

In the belief that the new method will prove of service, the analysis will be given in full for future reference, for immediate use by engineers who will determine experimentally the coefficients, c and f, for any soil in question.

The computation will refer to the revised section of the dam, Plate XII, but the cut-off wall will be ignored (which is on the side of safety), and the width of foundation (as estimated conservatively from the drawing) will be taken as 52 ft.

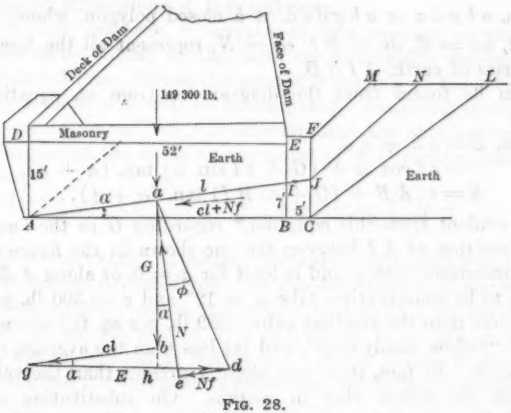


FIG. 28.

Thus, in Fig. 28, the width of foundation of the dam, $D\,E = 52$ ft.; the anchoring wall, or arm, extends from D to A, 15 ft., the wall being just to the left of $A\,D$. The toe-wall extends downward from E to I, 8 ft. To the right of this is earth, with the free surface, $E\,F\,M\,N$.

The analysis will proceed along the lines outlined by the author, but cohesion will be included and the resistance to sliding along $I\,J$ or $B\,C$ will be ignored. The problem then consists of finding the horizontal component of the resistance to sliding along planes such as $A\,I$ and $J\,N$ or along $A\,B$ and $C\,L$. Assuming the earth to weigh 100 lb. per cu. ft., the weight of earth, $A\,I\,E\,D$, is 59 800 lb., which, added to the weight of the dam and of the water on the deck,

Mr. Cain. $2\,239\,400 \div 15 = 149\,293$ lb. per lin. ft. of dam crest, gives the weight on $A\,I = 209\,000$ lb. Denote this weight by G, the length, $A\,I$, by l, and its inclination to the horizontal by α. If $N = a\,e$ is the normal reaction of the plane, $A\,I$ (making the angle, α, with the vertical), then the resistance along the plane, acting to the left, to a horizontal force, E, tending to cause sliding along $A\,I$ to the right, is $c\,l + N\,f$. The friction component is $N\,f = \overline{de}$ and this, combined with $N = \overline{ea}$, gives a resultant, $\overline{da}$, making the angle, ϕ, with the normal $\overline{ae}$, since $f = \tan.\ \phi$.

Hence, if we lay off, to scale, $\overline{ab} = G$, then draw $\overline{bg} = c\,l$ parallel to $I\,A$; from g, draw a horizontal, $\overline{gd}$, to the intersection, d, with the line from a, making the angle, ϕ, above the normal $\overline{ae}$, then $\overline{gd} = E$, which is equal and opposed to the horizontal passive resistance to impending sliding up the plane, $A\,I$. This follows because the polygon of forces, $a\,b\,g\,d\,a$ or $a\,b\,g\,d\,e\,a$, is a closed polygon, where, $\overline{ab} = G$, $\overline{bg} = c\,l$, $\overline{gd} = E$, $\overline{de} = N\,f$, $\overline{ea} = N$, represent all the forces acting on the mass of earth, $A\,I\,E\,D$.

E can be found from the diagram or from an equation easily deduced.

Thus, $E = g\,h + h\,d$

$$= c\,l \cos.\ \alpha + (G + c\,l \sin.\ \alpha) \tan.\ (\alpha + \phi).$$

$$E = c\,.\,A\,B + (G + c\,.\,B\,I) \tan.\ (\alpha + \phi) \ldots\ldots\ldots\ldots (3)$$

It is evident from this equation,* regarding G as the load on $A\,I$ for any position of $A\,I$ between the one shown in the figure and $A\,B$, that E diminishes with α and is least for $\alpha = 0$, or along $A\,B$.

Now, to be conservative, take $\phi = 12°$ and $c = 300$ lb. per sq. ft., which is less than the smallest value (389 lb. per sq. ft.) given in Table 8 for the "yellow, sandy clay", and far less than the average, $c = 2\,260$ lb. per sq. ft. In fact, it is only slightly greater than the value (280) found for the yellow clay in motion. On substituting numerical values, $A\,B = 52$, $B\,I = 7$, $\alpha = 7°\ 30'$, $\phi = 12°$, $c = 300$, in Equation (3), we derive the resistance, exerted horizontally, to impending sliding up the plane, $A\,I$,

$$E = 90\,300 \text{ lb.}$$

To find the similar resistance to sliding along the horizontal plane, $A\,B$, first find the weight of earth, $A\,B\,E\,D = 78\,000$ lb., and add to 149 000 to get the G corresponding, $G = 227\,000$ lb. Then, making $\alpha = 0$ in Equation (3), or using Equation (1), we find the resistance to sliding along the plane, $A\,B$,

$$E = 227\,000 \tan.\ 12° + 300 \times 52 = 64\,000 \text{ lb.}$$

* On putting $(G + c\,.\,B\,I)$ in form $\left(227\,000 + A\,B \tan.\ \alpha \left(c - \frac{A\,B}{2}\right)\right)$, the weight of dam, water over it, and earth, $A\,B\,E\,D$, being 227 000 lb.

Mr. Cain.

If we assume the coefficients, c and f, the same along $D\,E$ (for concrete on earth) as above, or $c = 300$ lb. per sq. ft., $\phi = 12°$, we find the resistance to sliding along $D\,E$ to be,

$$149\,000 \times 0.213 + 300 \times 52 = 47\,000 \text{ lb.}$$

If it is recalled that it was found above, that the stability of the old dam was possible when $c = 660$ lb. per sq. ft., $\phi = 13°\ 50'$, then the values, c and ϕ, assumed along $D\,E$, appear to be conservative.

The horizontal component of the water pressure per foot of length of crest is $1\,218\,200 \div 15 = 81\,000$ lb. Of this, 47 000 lb. is carried by the earth directly down to the planes, $A\,I$ or $A\,B$, the remainder, 34 000 lb., being carried to the anchoring arm along $A\,D$, by which it is finally transmitted to the earth to the right of $A\,D$. The average pressure on the earth along $A\,D$ is $34\,000 \div 15 = 2\,267$ lb. per sq. ft., which is perhaps not so great as to cause flow, though the exact distribution of stress along $A\,D$ is unknown.

It is well, however, to enquire if this pressure of the arm, $A\,D$, may not cause sliding of the earth up some plane through A, shown by the dotted line. Hence the passive resistance of the earth to sliding up such a plane will next be investigated. Assuming that the reaction of the anchoring wall on $A\,D$ is horizontal, the unit horizontal passive resistance, a, of the earth at any point of $A\,D$ can be found from the equation,*

$$a = b \tan.^2 \left(45° + \frac{\phi}{2}\right) + 2\,c \tan. \left(45° + \frac{\phi}{2}\right),$$

where b = the weight, in pounds per square foot, acting on a horizontal plane at the point considered. As the distribution of stress on $D\,E$ is not given, assume it to be uniform, so that at D, $b = 149\,300 \div 52 = 2\,870$ lb. per sq. ft.; and at A, $b = 2\,870 + 15 \times 100 = 4\,370$ lb. per sq. ft. Hence, taking, as before, $\phi = 12°$, $c = 300$ lb. per sq. ft., the equation gives the unit passive resistance, acting horizontally to the left,

at D: 5 120 lb. per sq. ft.;
at A: 7 400 lb. per sq. ft.

As the flow of the earth is supposed to occur at 4 000 lb. per sq. ft., it is seen that sliding up the dotted plane will not occur when the maximum permissible stress on AD is taken at 4 000 lb. per sq. ft., as given by the author. If the permissible value to prevent flow had been assumed to be greater than 7 400 lb. per sq. ft., then the maximum unit compression at A must be taken at 7 400 lb. per sq. ft. or less; otherwise the earth at A would tend to slide up the dotted plane, which makes an angle, $45° + \frac{\phi}{2} = 51°$, with the vertical.

* Cain's "Earth Pressure", p. 192.

Mr. Cain.

It now remains to compute the passive resistance, exerted on $F\,J$ or $F\,C$, of the earth to sliding up the proper planes of rupture, $J\,N$ or $C\,L$, corresponding. The graphical construction for effecting this will be given presently; but, to complete the present investigation, the result may be anticipated that the passive resistance on either $F\,J$ or $F\,C$ exceeds the safe compressive stress of the earth, so that the latter will limit the available resistance. The unit passive resistance at the free surface is not zero, but a very appreciable quantity, as will be shown eventually, and reasons will be given why an average pressure on $F\,J$ or $F\,C$ of 3 000 lb. per sq. ft. can be allowed without fear of the compressive strength of the earth being exceeded, or flow being imminent. Thus, the total compression, acting horizontally, that will be allowed on $F\,J$, 9 ft. in depth, is,

$$3\,000 \times 9 = 27\,000 \text{ lb.},$$

and on $F\,C$, 16 ft. in depth,

$$3\,000 \times 16 = 48\,000 \text{ lb.}$$

It has been shown previously, omitting any resistances along $I\,J$ and $B\,C$, that the horizontal component of the resistance to sliding along $A\,C$ is 64 000 lb., and along $A\,J$, 90 000 lb.; hence the total horizontal component of the resistance,

$$\text{along } A\,C \text{ and } C\,F = 64\,000 + 48\,000 = 112\,000 \text{ lb.}$$
$$\text{and along } A\,J \text{ and } J\,F = 90\,000 + 27\,000 = 117\,000 \text{ lb.}$$

Both of these totals exceed the horizontal component of the water pressure, 81 000 lb.; so that, if the assumed values of, $c = 300$ lb. per sq. ft. and $\phi = 12°$, are safe values, the dam is secure against sliding, for the conditions assumed, along the planes taken. The conclusion will not be altered if any plane intermediate between $A\,J$ and $A\,C$ is taken in place of either of these planes. From what precedes, it seems that $c = 300$ lb. per sq. ft. is a safe value, but there is uncertainty as to the value of ϕ. If we assume $\phi = 4° 23'$ (tan. $\phi = 0.0767 = f$), it will be found that, using $c = 300$, as before, the horizontal component of the water pressure is exactly equal to the resistance exerted along $A\,C$ and $C\,F$. For a less value of ϕ, sliding would occur. From Table 7, the value $\phi = 4° 23'$ is seen to be a barely possible one, though the probable value is greater; hence, with the incomplete data as to c and ϕ, it can only be asserted, for the loading of the author's Case I, that this investigation shows that the dam is most probably safe against sliding. The investigation for the loading under Case II, or "under the most severe conditions within limits of reason", page 957, is exactly similar to the foregoing, so that only results will be given.

The uplift water pressure was subtracted from the former load on the foundation, giving a net load, per foot of crest, on the foundation

of 90 400 lb. Of course, this uplift pressure must not be taken in addition from the weights, $A\,I\,E\,D$ or $A\,B\,E\,D$, of earth, since, from the unit water pressure (say) just to the right of A, acting upward, is to be subtracted the weight of a column of water of height, $A\,D$, and horizontal section unity, which gives, precisely, the uplift at the level, $D\,E$; so that the weight of earth, $A\,I\,E\,D$ or $A\,B\,E\,D$, is not to be increased by the weight of water above $A\,I$ or $A\,B$, or diminished in any way, since the uplift pressure has already been subtracted from the load on $D\,E$. The total horizontal force acting on the dam, due to water pressure and ice, is 101 300 lb. per lin. ft. Mr. Cain.

By an investigation similar to the foregoing, it is found, for $c = 300$ lb. per sq. ft., $\phi = 12°$ and the compression on $C\,F$ limited to 3 000 lb. per sq. ft., that the total horizontal resistance along $A\,C$ and $C\,F$ amounts to 99 400 lb., and along $A\,J$ and $J\,F$ to 96 500 lb. However, for $c = 388$ lb. per sq. ft., $\phi = 12°$, the least resistance is equal to the water and ice pressure, 101 300 lb.; so that the dam is secure against sliding for either Case I or Case II, if $c = 390$ lb. per sq. ft. and $\phi = 12°$.

It is interesting to know the amount of security when $c = 660$ lb. per sq. ft., $\phi = 12°$. It is found, for these values, that the horizontal resistance exerted along $A\,B$ and $C\,F$ amounts to 118 000 lb., and along $A\,I$ and $J\,F$, to 116 000 lb. The latter value exceeds the water and ice pressure by 15 per cent. Since it was found above that the old dam was just stable for $c = 660$ lb. per sq. ft., $\phi = 13°\ 50'$, the values assumed, $c = 660$, $\phi = 12°$, seem to be not unreasonable. Again, for $c = 660$, $\phi = 12°$, the horizontal resistance to sliding along the foundation is, for Case II, $90\,400 \times 0.243 + 660 \times 52 = 53\,600$ lb.; hence the anchoring wall at $A\,D$ carries,

$$101\,300 - 53\,600 = 47\,700 \text{ lb.}$$

or, $47\,700 \div 15 = 3\,180$ lb. per sq. ft., average pressure.

As stated above, the resistance along BC (5 ft. in length), as well as that along IJ, was neglected, there being but little weight over parts of these surfaces; also, the cut-off wall was omitted, or it was supposed to be cracked at A. There is evidently some resistance from the omitted portions.

It must be distinctly understood that, although probable values for c and f for Cases I and II, have been found above, it is not asserted that these are the real values exerted. More extended experimental data as to these coefficients are required before definite results can be predicted.

It remains to find the passive resistance of the earth to the right of $C\,F$ or $J\,F$ to sliding up some plane, as $C\,L$ or $J\,N$. Although the assumption of a plane surface of rupture, as $A\,B$ or $A\,I$, for the earth under the dam, is doubtless near the truth, the same cannot be said for

Mr. Cain. the earth below the dam, of the irregular free surface, *F M L*. Theory shows that, except when the free surface is level, the surface of rupture is curved; so that when it is, of necessity, assumed to be plane, in the graphical construction that follows, the results must be treated as only an approximation to the truth, and a factor of safety must be used. Here, again, no experiments as to passive resistance have been made, so that we are absolutely in the dark as to the true surface of rupture and the resulting passive thrust.

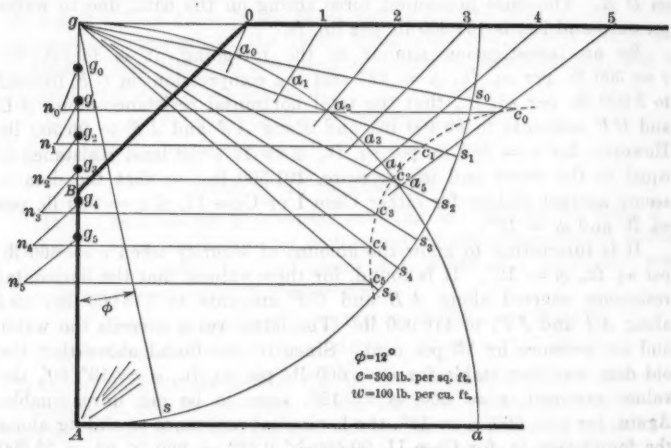

FIG. 29.

The graphical construction alluded to is given in Fig. 29, where $A\ B = 16$ ft., $B\ g = 11.5$ ft., and $\overline{go} = 11.5$ ft.; $A\ B$ (= $C\ F$ of Fig. 28) being vertical and $\overline{0\,5}$ (= $M\ L$ of Fig. 28) being horizontal. It is desired to know the least force, acting horizontally to the right on $A\ B$, that will cause sliding up some plane of rupture $A\ 4$. Draw a number of trial planes of rupture, $A\ 0$, $A\ 1$, . . ., and draw $A\ a$ horizontal. Then, with A and some point, g, on the vertical, $A\ B$, produced, as centers, and with the same radius, $A\ g$, describe two arcs of circles, $a\ a_0$ and $A\ s\ s_0$. Assuming $\phi = 12°$, lay off $A\ g\ s = \phi = 12°$ and, with dividers, lay off the chord, $s\ s_0$ = the chord, $a\ a_0$, the chord, $s\ s_1$, = the chord, $a\ a_1$, etc., hence we have the equality of the angles, $s\ g\ s_0 = a\ A\ a_0$, $s\ g\ s_1$, $= a\ A\ a_1$, $s\ g\ s_2 = a\ A\ a_2$, etc. Then $g\ s_0$, $g\ s_1$, $g\ s_2$, . . . , make the angles, ϕ, above the normals to the planes, $A\ 0$, $A\ 1$, $A\ 2$, . . . , respectively. This is easily seen by referring to the force diagram of Fig. 28, in which it is observed that $a\ d$ makes the angle, $\phi + \alpha$, with the vertical. Similarly, in Fig. 29, if (say), the angle $a\ A\ 4 = \alpha$, then $A\ g\ s_4 = \phi + \alpha$, since we laid off

$s\ g\ s_4 = a\ A\ a_4 = \alpha$; hence, as in the case of $a\ d$ in Fig. 28, $g\ s_4$ makes the angle, ϕ, above the normal to the plane, $A\ 4$. It is convenient here to lay off the angle $\phi = A\ g\ s$ first, and then lay off the successive α's above $g\ s$. Mr. Cain.

Let it be assumed that the earth weighs 100 lb. per cu. ft. and that the coefficient of cohesion is $c = 300$ lb. per sq. ft.

The next step is to compute the weight of the successive trial prisms of rupture, $A\ B\ 0$, $A\ B\ 0\ 1$, $A\ B\ 0\ 2$, . . . , and lay off to scale on the vertical, $g\ A$, $g\ g_0$, $g\ g_1$, $g\ g_2$, . . . , to represent these successive weights. If, on the horizontal, $g\ 0\ 4$, we construct $\overline{0\ 1} = \overline{1\ 2} = \overline{2\ 3}$, . . ., the triangles, $A\ 0\ 1$, $A\ 1\ 2$, . . . , are all equal in area, so that the total areas can be computed quickly by successive additions. The thickness of the prisms perpendicular to the plane of the paper is assumed as unity, so that areas and volumes are represented by the same numbers.

We next measure the lengths, $A\ 0$, $A\ 1$, $A\ 2$, . . . , to the scale of distance, and multiply the lengths, in feet, by $c = 300$, to find the successive cohesive forces acting downward (opposed to impending motion) along the planes, $A\ 0$, $A\ 1$, . . . , respectively. Lay off, to the scale of loads, $g_0\ n_0$, $g_1\ n_1$, . . . , parallel, respectively, to $A\ 0$, $A\ 1$, . . . , and equal to the cohesive forces acting along these planes. From n_0, n_1, . . ., draw horizontals to intersections, c_0, c_1, . . ., with $g s_0$, $g s_1$, . . .; then the smallest of the lengths, $n\ c$, to the scale of loads, will give the passive earth thrust on $A\ B$. In this figure, $n_4\ c_4$ is the shortest of the lines, $n\ c$, and it measures to the scale of loads, 69 300 lb., which is the passive thrust required, and $A\ 4$ is the corresponding plane of rupture. The method, just outlined, consists in treating in turn, $A\ B\ 0$, $A\ B\ 0\ 1$, . . . , as trial prisms of rupture and constructing the successive polygons of forces, $g\ g_0\ n_0\ c_0\ g$, $g\ g_1\ n_1\ c_1\ g$, . . ., similar to the polygon, $a\ b\ g\ d\ a$, of Fig. 28. The polygon, $g\ g_4\ n_4\ c_4\ g$, is found to have the least value of the thrust, $n_4\ c_4$, hence motion is impending for this thrust on $A\ B$, only along the plane $A\ 4$, since a greater thrust on $A\ B$, acting from left to right, is required to cause impending motion up the other trial planes of rupture. The forces in equilibrium acting on the true and only prism of rupture, $A\ B\ 0\ 4$, are, to scale, $g\ g_4$ = weight, in pounds, of $A\ B\ 0\ 4$, $g_4\ c_4$ = cohesion on $A\ 4$, acting down and parallel to $A\ 4$, $n_4\ c_4$ = thrust on $A\ B$, $c_4\ g$ = resultant of N and N tan. ϕ, where N = normal reaction of the plane, $A\ 4$, and N tan. ϕ is the friction acting down (opposed to impending motion) along the plane, $A\ 4$. The resultant of N and N tan. ϕ, thus makes the angle, ϕ, above the normal to $A\ 4$, as constructed in the beginning.

For the thrust, $n_4\ c_4$, on $A\ B$, acting from left to right, motion is impending not only along the plane, $A\ 4$, but upward along the plane,

Mr. Cain.

$A\ B$; hence, strictly, cohesion and friction are exerted downward on the plane, $A\ B$. Neglecting the cohesion, this would require that the lines of the type, $n\ c$, should be inclined below the normal to $A\ B$, or below the horizontal, at the angle, ϕ. Hence intersections, as c_4, will move down the corresponding $g\ s_4$, so that $n_4\ c_4$ and its horizontal component will be greater than before. The same is true for all the trial thrusts, of which the least is to be taken as the true one. The horizontal component of the true thrust, thus found, is greater than that found before, where the pressure on $A\ B$ was supposed to act horizontally.

From lack of any experimental data concerning passive thrust, it seems best, at present, to take the smaller thrust, corresponding to a horizontal pressure on $A\ B$, since the surface of rupture is curved and the assumption made that it is plane may possibly give results far from the truth. Hence, in computing the various values of the passive resistance to the push of the earth to the left of $C\ F$, Fig. 28, acting to the right, the push or thrust was taken as acting horizontally, as in Fig. 29.* For accuracy, other planes, lying near $A4$, should be tested in order to ascertain the minimum thrust represented by a line of the type, $n\ c$, or calculation can be resorted to. In fact, Equation (3), referring to Fig. 28, is directly applicable to each trial prism of rupture, provided G represents its weight.

Thus, in Fig. 30, let,

G = the weight of the trial prism of rupture, $A\ D\ M\ I$;
$x = A\ B$ = the horizontal projection of $A\ I$;
$y = B\ I$ = the vertical projection of $A\ I$;
α = the angle, $B\ A\ I$;

whence $\tan.\ \alpha = \dfrac{y}{x}$.

Then Equation (3) takes the form,

$$E = c\ x + (G + c\ y)\ \tan.\ (\alpha + \phi) \ldots\ldots\ldots\ldots (4)$$

By the use of this equation, it is not necessary to draw Fig. 29 at all, as the equation can be applied to each trial prism of rupture in turn. Thus, for $\phi = 12°$, $c = 300$, for the plane, $A4$, of Fig. 29, $x = 31.5'$, $y = 27.5'$; therefore $\tan.\ \alpha = \dfrac{y}{x} = 0.873$; therefore

* It may occur to one who has read pages 180–181 of the writer's "Earth Pressure", that, for the slope, FM, of Fig. 28, the theory pertaining to the uniform slope of indefinite extent, may be applicable; but, since FM is of limited extent, and the pushing force exerted on CF, from left to right, does not act parallel to FM, the conditions postulated for this theory do not obtain, and the theory is inapplicable. The surface, FM, makes an angle, $i = 45°$, with the horizontal, and if it was of indefinite extent, below and above F, slipping would occur at a depth, $x_0 = 7.62$ ft., when $\phi = 12°$, $c = 300$ lb. per sq. ft., by the theory alluded to, and the passive thrust, acting parallel to the surface, would be much smaller than that found above. If FM was large, say, 100 ft., at the same point of the slope, the theory might be approximately applicable; but, even then, the only effect would be a readjustment of the free surface contour to a new surface consistent with equilibrium.

$\alpha = 41° 07'$; also $G =$ the weight of $A\ B\ 0\ 3 = 36\,700$ lb.; whence, by Equation (4), $E = 69\,400$ lb. Mr. Cain.

Similarly, for the plane, $A3$, $x = 26.5$, $y = 27.5$, whence $\alpha = 46° 8'$; also $G =$ weight of $A\ B\ 0\ 3 = 29\,863$, and finally, $E = 69\,250$ lb. For a trial plane of rupture from A to a point midway between points (3) and (4), it is similarly found that $E = 69\,000$ lb.; hence this plane can be regarded as the true plane of rupture, and the thrust, 69 100 lb. (the least of the three), as very nearly the true thrust.

The passive thrusts for all the cases examined are as follows (referring to Fig. 28):

$c = 300$, $\phi = 12°$, passive thrust on $FJ = 34\,300$ lb.
" " " " " $FC = 69\,100$ lb.
$c = 660$, $\phi = 12°$, " " " $FJ = 54\,800$ lb.
" " " " " $FC = 95\,000$ lb.

In the first case, N is to the left of M; for the other cases, both N and L were found to be to the right of M. These thrusts exceed the compressive strength of the material along FJ or FC, and hence they cannot be utilized in estimating the resistance of the dam against sliding, as previously noted.

It has been stated previously that the unit passive thrust at the free surface of the earth was not zero. To find approximately its amount at the point, D, let us find the thrust on a vertical plane extending 1 ft. below D, Fig. 30, by repeated use of Equation (4). The minimum value of E, which is the true thrust, is found to be 2 700 lb. per sq. ft. It corresponds to $\alpha = 61°$, nearly. By consideration of the total thrusts on the areas, FJ and FC of Fig. 28, it was estimated that the unit thrust at C was about double that at F. The unit thrust is not uniformly increasing, but varies about as shown by the little arrows in Fig. 30.

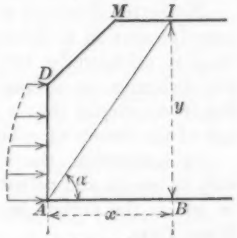

FIG. 30.

The unit compression on FC, Fig. 28, can be supposed to follow the same law, though, for simplicity, it can be regarded as uniformly increasing from a stress of 2 000 lb. per sq. ft. at F to double this, or the maximum allowable, 4 000 lb. per sq. ft., at C. This gives an allowable average stress on FC of 3 000 lb. per sq. ft., as used above.

It is seen from this investigation that the author is warranted in using a larger average safe stress on FC than the specified 2 000 lb. per sq. ft.

It may be observed that, if the force tending to cause sliding of the dam is entirely resisted along the plane, AB, then only the active

Mr. Cain. pressure of the earth to the right of FC is exerted. If, then, the resistance along AB is supposed to diminish, first the active thrust of the mass, $CFML$, will be overcome and then more or less of the full passive thrust of this mass will be exerted, the amount always being less than that which would exceed the safe compressive stress of the earth, or would cause flow of the material along CF. Consequently, it does not appear that the passive resistance of any pile of earth placed below a dam to help resist sliding will ever come into play unless there is a slight movement of the dam down stream, since earth is not a rigid body.

A year or so ago, the writer's attention was called to the case of a high dam, where a large pile of earth was placed below and against the dam, to prevent possible sliding. He stated then that the coefficients of friction and cohesion were both needed to investigate fully the extra resistance to sliding supplied by the earth. He is glad of this opportunity to offer the full solution for such cases. Whatever the free surface contour, the graphical method of Fig. 29 offers a quick, approximate solution, though it is well, for the reasons stated, to apply a factor of safety to the result, or otherwise to use conservative values of c and f.

No better illustration could be given of the need of "comprehensive experimentation to determine the coefficients of friction and cohesion," than is afforded by this constantly recurring problem of estimating the resistance to sliding of dams and retaining walls. The writer is firmly convinced that a correct solution can only be attained by the use of the theory of coherent earth.

In conclusion, the writer wishes to state his appreciation of the very thorough and painstaking manner—down to the minutest details—in which the author has done the work of reconstructing the Stony River Dam.

Mr. Gregory. CHARLES E. GREGORY,* ASSOC. M. AM. SOC. C. E.—A paper of this kind is unusually interesting, because it deals with the failure of a structure. The speaker believes that one can always learn very much more from the failure of a structure than from any discussion of what one believes ought to happen in accordance with theories.

The author has given a most lucid and well-written description of how he corrected the mistakes of the first dam, and has most ingeniously met the difficulties of the problem while utilizing the portions of the old dam which remained after the failure.

The reconstruction of this dam is an interesting subject, because it deals with a number of uncertainties pertaining to both the site and the type of dam, and uncertainties are always interesting. About the only relatively definite elements in the whole problem are the strength

* Mt. Kisco, N. Y.

of concrete and steel. Nearly everything else is open to more or less uncertainty. Notwithstanding this, the speaker believes all will admit that any large dam should be built so that its safety cannot be questioned, and one cannot say that any structure is safe until the uncertainties have been eliminated. Mr. Gregory.

In this case the type of dam and the site having been determined, there remain a great number of very uncertain features to be considered. The author has pointed out most of them, and has told how they were removed.

In any hollow dam, the uplift is the great doubtful feature and the great enemy of a dam of this type. There is no way of knowing to a certainty just what the uplift pressure is and how it is distributed. In designing a dam of this type, certain assumptions are made as to this pressure. It is assumed that if uplift exists, it can be controlled and limited by the weep-holes. Therefore, numerous weep-holes are placed in the foundation, and are supposed to relieve the upward pressure, and limit it to a relatively small amount. The cut-off wall must be effective, and must cut off the water from the impounded reservoir.

It is common experience that it is exceedingly difficult to build a cut-off wall, of any great depth and length, which will be absolutely water-tight. A concrete wall of great length will shrink and crack, in spite of anything that can be done to prevent it. Construction joints form weak planes, if not actual joints. All these conditions are favorable to leakage, even when one is successful in securing impervious rock foundation. Some water is bound to get through, and then it is bound also to show itself under the bottom of the dam.

When weep-holes are provided and are effective, they will allow this water to escape and relieve the pressure, but if they are not effective, the upward pressure will obtain. If they are effective, however, the water flowing through the soil under the bottom of the dam is a new source of danger.

A safe structure should not be menaced by flotation or by undermining. The flowing water from the weep-holes is certain to carry with it more or less soil, especially if it consists of fine, light grains; and undermining of the bottom of the dam will gradually occur. Eventually, the flow will become greater, heavier grains of soil will be carried, and ultimately there will be sufficient undermining to cause settlement and cracking, increasing the upward pressure so as to cause the dam to overturn or slide.

Probably this dam started to fail by overturning due to undermining. As soon as the tendency to overturn developed tension at the upper toe sufficient to open a joint and admit the water, the upward pressure floated the whole section off its base. The failure was probably a combination of overturning and sliding.

Mr. Gregory.

The speaker has not made any check computations whatever of the original structure, but from the author's statement of the various forces acting on this dam it would seem that, unless high coefficients of friction are assumed for the base, it would not have been safe from sliding. There seems to be no good ground for assuming high coefficients for a soil which is saturated with upward flowing water to the weep-holes.

In the speaker's opinion, the initial mistake was made in selecting a dam of this type for such a site. Although the speaker has not visited the site, and knows nothing about it, except what is disclosed in the paper, there appears to be in the vicinity considerable clay, gravel, and sandy clay which would be excellent material for an earth dam. An earth dam could have been built on this site economically, and would have eliminated nearly all the very uncertain features which obtain with this hollow concrete dam; the speaker believes an earth dam is the proper type for this site.

Another interesting part of the paper is the discussion of the spillway capacity. The author certainly has increased the capacity of the original spillway to a point beyond all precedent. The speaker believes that any spillway should have a very safe capacity. It should be large enough to care for the very largest storm that can possibly be conceived of, but the speaker believes that, in this case, the author has surely gone beyond the necessary limit. A flood as great as that provided for by the new spillway certainly could be produced only by a rainfall far greater than the maximum curve of rainfall for the eastern United States, as indicated by A. N. Talbot, M. Am. Soc. C. E. This curve is supposed to cover the greatest rainfall in this part of the country.

On page 930, the author cites certain storms of great intensity for 24 hours, but does not give the rate for the critical time for the water-shed. Probably a rainfall of 2 or 3 hours would be much more nearly the critical period for this water-shed. Fig. 31 and Table 9 present data from the automatic rain gauge in Central Park, New York, recorded continuously since 1869, and are self-explanatory. The maximum curve for Greater New York gives rates materially outside the Talbot curve, and is shown on Fig. 32.

On the illustration of the new spillway (Plate X) is shown a joint between the buttress wall and the slab covering the bays. This joint is filled with three-ply tar-paper. Apparently, such paper was not used in the old dam, or it would not have shown the bond that it did along those joints.

It would seem to the speaker that the placing of tar-paper in the joints of this dam, or in any dam, would be very poor practice. In the speaker's opinion, tar-paper could not be classed as a permanent material which would stand up under wet and dry, freezing and thaw-

Mr. Gregory.

ing, as should have been provided in a permanent structure. These joints, though they should have been made free to move, should have had some more permanent methods of stopping leakage. Even a plain, smooth joint, without any filling, would have been far better than the tar-paper. Some form of metal tongue across the joint would have been still better.

When designing the Ashokan and Kensico Dams, of the Catskill Water Supply System, the speaker had occasion to divide these gravity masonry dams into sections for the purpose of taking up the contraction due to temperature changes. In the Ashokan Dam the joint was formed with concrete blocks, as shown on Fig. 33, and the leakage through the opening of the joint was prevented by constructing a 6-in. offset, with a face very accurately finished in a plane parallel to the longitudinal axis of the dam, so that when the joint opened the concrete surfaces would slide on each other without opening.

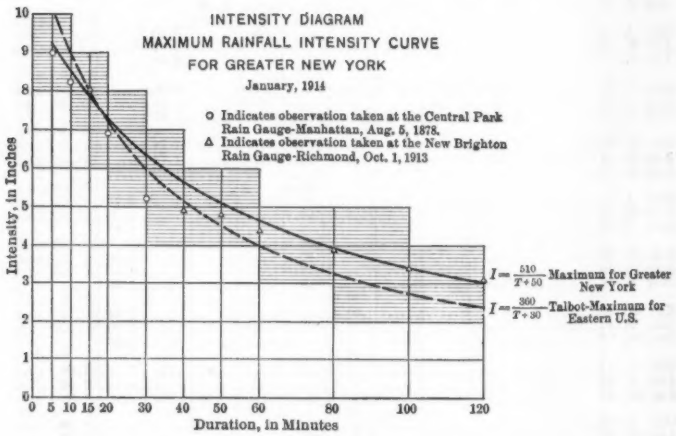

FIG. 32.

Just down stream from this offset, as shown, is the drainage well to collect and carry to a lower gallery whatever leakage might come through the joint. Experience has shown the leakage through the fifteen joints of this dam, aggregating about 1 500 lin. ft. of exposed joint, to have been about 450 000 gal. per day as a maximum, and to have been reduced to about 25 000 gal. per day on November 2d, 1916.

In the Kensico Dam, similar joints were provided with a copper strip arranged diagonally across the sliding joint, so that, when the

Mr. Gregory.

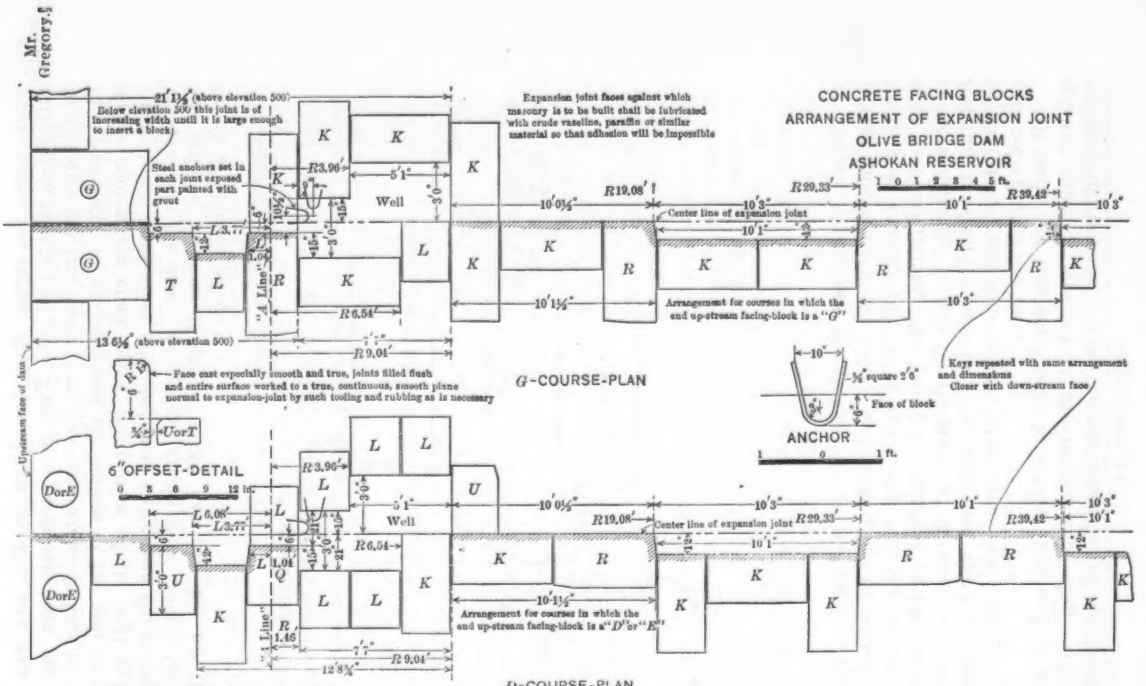

FIG. 33.

Mr. Gregory.

joint opens, the copper strip (as shown on Fig. 34) will crumple rather than tend to pull out. These structures have been very effective in all joints but two where there was considerable leakage at first, due to a poor batch of concrete near the bottom of the well in one case, and a contraction crack below the bottom of the well and copper strips in two cases which admitted more water than the entire twenty-two joints in the dam. After these cracks were grouted the leakage was reduced to from 13 000 to 18 000 gal. per day for the 1 900 lin. ft. of exposed joint.

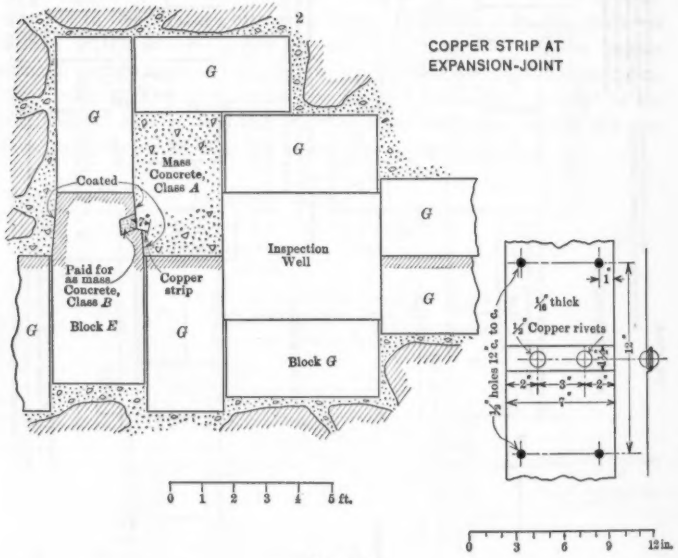

FIG. 34.

Mr. Grant.

KENNETH C. GRANT,* M. AM. SOC. C. E. (by letter).—This paper is very interesting to the writer, who made a careful examination of the dam on January 16th, 1914, and agrees with the author's conclusions as to its failure. The writer is impressed by the thoroughness of the studies and designs for the repair of the dam, and cannot but feel that it is unfortunate that the same care was not taken in the original design and construction, when equal safety could have been obtained at much less cost.

All readers of this paper must have been impressed by the large spillway capacity provided in the reconstructed dam. The writer was particularly pleased to see the retarding effect of the storage above

* Washington, D. C.

Mr. Grant.

spillway level worked out by actually routing the assumed maximum flood through the reservoir. The usual method of expressing spillway capacity, in terms of run-off per square mile of drainage area, does not tell the whole story. If the reservoir has a large surface area at spillway level, a rise of a foot in the water surface represents a very considerable storage capacity; and the maximum flood that can safely be taken care of by spillway and storage combined may be much greater than in the case of a reservoir with the same spillway capacity, but a small area of water surface. In the assumed maximum case shown on Fig. 15, the maximum spillway discharge amounted to about 1 600 sec-ft. per sq. mile, and the assumed flood causing this outflow reached a maximum of nearly 2 600 sec-ft. per sq. mile. Thus, the spillway capacity of 1 840 sec-ft. per sq. mile given by the author really means that it would take a flood about two-thirds larger than this to overtop the dam.

This reducing action, which every full reservoir exerts on a flood wave, is the same in principle as the control effected by retarding basins such as those which are to be built for the protection of the Miami Valley in Western Ohio, except that, in the latter case, the reduction is much greater, inasmuch as the entire capacity of the basins is available for flood storage. The writer has noted that the capacity of some of the flood-control reservoirs in Europe, in which the conduits can be closed by gates, is correctly considered to be the total capacity up to the elevation at which the spillway discharge reaches the maximum outflow that can be safely delivered to the channel below.

It may be of interest to explain briefly the method found to be the simplest for routing floods through the Miami Valley retarding basins, by applying it to the flood wave assumed by the author in Fig. 12. In the method here to be described, the time interval is fixed, and the rate of outflow is obtained by trial. The rate of inflow is fixed by the adopted time interval, and the trial rate of storage and elevation of reservoir surface are fixed as soon as the rate of outflow is assumed. As compared with the method of fixing the elevation of reservoir surface and finding the time interval by trial, this method has the advantage of enabling one to pick the breaks in the inflow curve, especially the peak, and the points where inflow equals outflow.

Fig. 35 shows a capacity curve of the Stony River Reservoir above spillway level, derived from Fig. 10; also a curve showing spillway discharges plotted against reservoir capacities, derived from Fig. 11. Fig. 36 shows the inflow and outflow curves, and Table 10 illustrates the method of recording the routing operation.

Conditions of starting similar to those given by the author, were assumed, namely, that, at 7 A. M., the outflow is equal to the inflow,

Mr. Grant.

or 100 sec-ft. From Fig. 35, this corresponds to a capacity of 208 400 000 cu. ft., or an elevation of 136.2.

Take a time interval of 1 hour. At this time the rate of inflow is 500 sec-ft. By trial, a rate of outflow at this time can quickly be

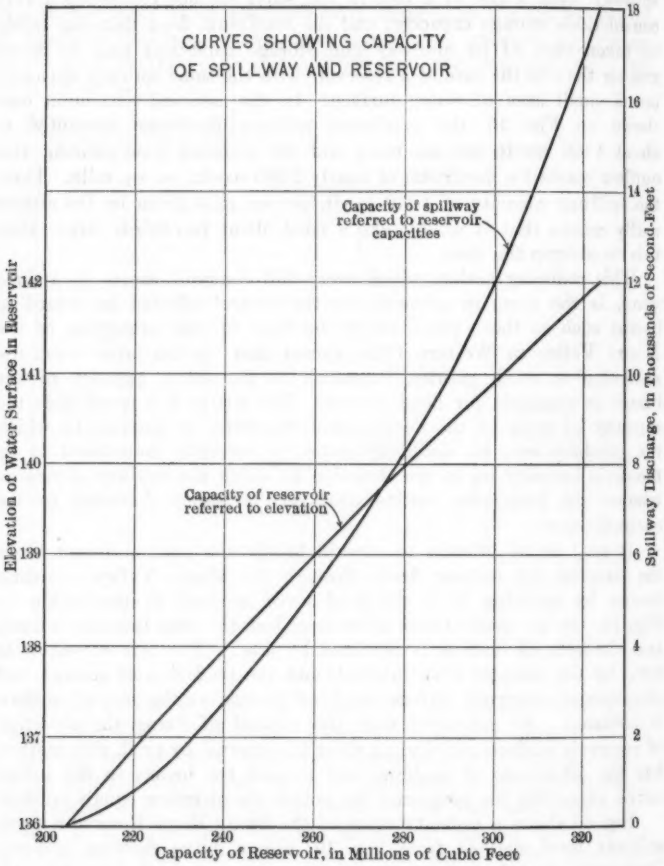

FIG. 35.

found such that the storage increment added to the storage already existing gives a total storage corresponding to the assumed outflow. Thus, by assuming a rate of outflow of 150 sec-ft. at the end of 1 hour, the rate of storage is 350 sec-ft., and the mean rate of storage is

175 sec-ft. Multiplying this by 3 600 gives the storage increment, in cubic feet, or 630 000 cu. ft. Adding this to 208 400 000, the storage at Elevation 136.2, gives 209 030 000 cu. ft., the total storage. Entering Mr. Grant.

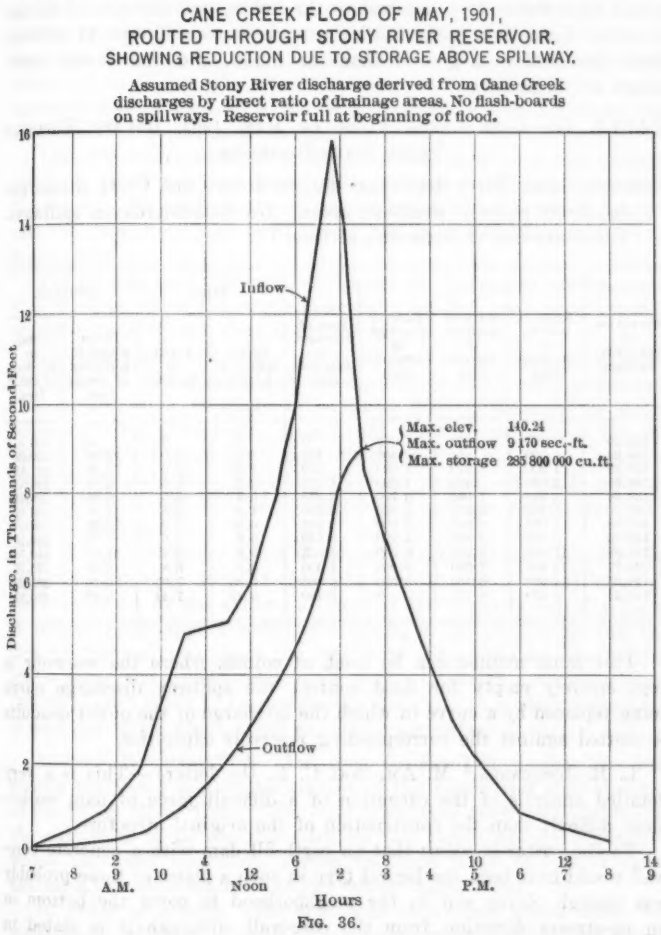

FIG. 36.

the spillway capacity curve on Fig. 35 with this reservoir capacity gives a discharge of 150 sec-ft., which checks the original assumption as to outflow. The elevation of reservoir surface, 136.24, is found by enter-

Mr. Grant.

ing the reservoir capacity curve on Fig. 35 with the total capacity, 209 030 000 cu. ft.

Continuing this operation, the maximum outflow is reached, at which time the outflow is equal to the inflow, and the rate of storage is zero. From this point until the water surface lowers to spillway level, the outflow is greater than the inflow, and the storage increments are negative.

TABLE 10.—CANE CREEK FLOOD OF MAY, 1901, ROUTED THROUGH STONY RIVER RESERVOIR.

Assumed Stony River discharges derived from Cane Creek discharges by direct ratio of drainage areas. No flash-boards on spillways. Reservoir full at beginning of flood.)

Elevation of reservoir surface.	Rate of inflow, in second-feet.	Rate of outflow, in second-feet.	Rate of storage, in second-feet.	Mean rate of storage, in second-feet.	Time.		Storage.	
					Increment, in hours.	Total, in hours.	Increment, in millions of cubic feet.	Total, in millions of cubic feet.
136.20	100	100	0	0	0	0	0	208.40

137.98	6 000	2 900	3 100	2 975	0.5	5.0	5.35	240.27
138.40	8 000	3 820	4 180	3 640	0.6	5.6	7.86	248.13
138.98	11 800	5 250	6 550	5 365	0.6	6.2	11.60	259.73
139.77	15 800	7 550	8 250	7 400	0.6	6.8	16.00	275.73
140.05	14 000	8 480	5 520	6 885	0.25	7.05	6.20	281.93
140.24	9 170	9 170	0	2 760	0.39	7.44	3.88	285.81

This same method can be used, of course, where the reservoir is kept entirely empty for flood control, the spillway discharge curve being replaced by a curve in which the discharge of the outlet conduits is plotted against the corresponding reservoir capacities.

Mr. Jorgensen.

L. R. JORGENSEN,* M. AM. SOC. C. E. (by letter).—This is a very detailed analysis of the execution of a difficult piece of dam work—more difficult than the construction of the original structure.

To the writer it seems that an earth-fill dam with a concrete core-wall would have been the logical type in such a place, as there probably was enough clayey soil in the neighborhood to cover the bottom in an up-stream direction from the core-wall, although it is stated in the paper that there was not enough suitable material to build a plain earth-fill dam.

* San Francisco, Cal.

Mr. Jorgensen.

Of course, the author was not concerned with what could have been done in the first place when he was confronted with the task of repairing and strengthening the dam.

The author makes extensive studies for spillway provision, and arrives at a high run-off figure which seems to be justified. The breakable flash-board support arrangement is a good feature, considering the fact that the treated pins were found to break within narrow limits of load, that is, within between 4 and 4.6 ft. of head above the base of the flash-boards.

Valuable information as to the frictional resistance and shearing value of clayey soil and shale under various conditions is given in the paper. The anchoring wall at the heel and the work of tying it into the dam must have been among the most difficult details of the construction.

The stresses used, 700 and 500 lb. per sq. in., are somewhat higher than those to which the writer is accustomed, but, with good concrete, should leave sufficient margin for safety.

The drainage system has evidently been a problem of no small magnitude in this case, where the foundation is of such a character that muddy water is likely to continue flowing through the drains where these are placed very close to the reservoir pressure. The fact that the vertical drain pipes only fill themselves, but do not overflow, seems to indicate that there could not be very much uplift pressure, although the writer does not understand why these pipes just fill but do not overflow.

It is specified under Class *C* concrete that boulders should constitute not more than 40% of the total volume, and it would be of interest—at least to the writer—to know if the quantity actually placed in this concrete approximated this figure, as he has always felt that 20% of "plums" was about the maximum that could be "thrown in", unless there was considerable hand work. Concrete containing many "plums" is not likely to be as water-tight as when a medium percentage is used, say, 20%, which is not so small a percentage at that.

Mr. Wegmann.

EDWARD WEGMANN,* M. AM. SOC. C. E.—The speaker has been greatly interested in this description of the repair and reconstruction of the Stony River Dam. The conditions were very unfavorable, and the author is to be complimented on the very thorough manner in which the work was done, giving the dam large factors of safety against all possible kinds of failure which might occur.

In order to correct some erroneous statements which have been made—some of them in print—the speaker must state his connection with the inception of this dam. He was engaged by the West Virginia Pulp and Paper Company, in the fall of 1911, to visit the site of a

* New York City.

Mr. Wegmann.

proposed storage reservoir in the mountains of West Virginia, which site had been selected by an engineer employed by the Paper Company for this purpose. Owing to the steepness of the river beds in that region, it was very difficult to find a suitable site for a storage reservoir, and the one finally chosen, after considerable investigation, appeared to be about the only one available. The speaker was requested by the Paper Company to give his opinion about this site, and to recommend the type of dam which he thought should be adopted.

In accordance with this request, he made one visit to the site of the reservoir, late in the fall of 1911, in the company of Mr. R. P. Bloss, the engineer of the Paper Company. At that time, only a few test pits had been excavated. They showed that the material overlying the rock consisted of yellow clay mixed with very fine sand, and underlain by compact blue clay. The rock surface was found to be at a considerable depth. The surface of the ground was covered with numerous boulders, and in most of the test pits boulders were found at a certain depth below the surface. An alarming feature was the fact that veins of some fine black material which looked like coal appeared in some of the test pits. Analyses, made later, proved that this material was not coal.

Both Mr. Bloss and the speaker were much impressed by the possibility that leakage under the proposed dam might occur through the black veins in the clay, unless a proper cut-off was provided to rock bottom, either by a masonry wall or by sheet-piling. The speaker requested Mr. Bloss to dig additional test pits and to make soundings with an auger, in order to determine, as nearly as possible, the position of rock bottom. This work was done subsequently, and, early in 1912, Mr. Bloss submitted to the speaker a cross-section of the valley of Stony River, showing the probable line of rock bottom.

Based on this cross-section and the data obtained by the test pits and borings, the speaker reported to the Paper Company as follows:

1.—That the site selected for the reservoir would be satisfactory, if the valley were closed by a well-constructed dam.

2.—That a masonry dam would cost more than $500 000, owing to the great depth to rock, which is about 45 ft. in the center of the valley.

3.—That an earth dam was out of the question, as no earth or gravel, for mixing with the clay at the site of the dam, could be found within a reasonable distance from the proposed reservoir.

4.—That the only type of dam which could be built at the proposed site, within a reasonable sum—say, from $150 000 to $200 000—was a hollow dam of reinforced concrete.

Mr. Wegmann.

After receiving the speaker's report, the Paper Company decided to construct a hollow dam of reinforced concrete, and requested the speaker to prepare a contract and specifications for this work. Three different companies which had had experience in this kind of construction were invited to submit plans and bids for the construction of a hollow dam of reinforced concrete, based on the cross-section of the valley prepared by Mr. Bloss. On this plan Mr. Bloss, in consultation with the speaker, had marked the least depth to which the foundation of the cut-off wall would probably be excavated, and the contract provided that if the foundation should go deeper, the additional work involved should be paid for as an extra. At both ends of the dam, where it was thought that the cut-off wall would probably not go down to rock, sheet-piling was shown.

Four different plans* for constructing the dam of reinforced concrete were received, with lump-sum bids, ranging from $143 000 to about $200 000, for building the dam to the depth shown on the cross-section of the valley.

Only one among the bidders, the Ambursen Hydraulic Construction Company, of Boston, Mass., had had much experience in the construction of dams of the proposed type. This Company had built, at that time, more than seventy dams of this kind, ranging in height up to 150 ft. All these dams were standing, and although one of them—that at Pittsfield, Mass.,† the cut-off wall of which had not been carried deep enough in a foundation of gravel—had been undermined at the center of the valley, the dam had merely sagged, but had not been ruptured. As the hole made under this dam by undermining had been 20 ft. deep, 53 ft. wide, and about 50 ft. long, both up stream and down stream, the structure had certainly shown remarkable strength. It had been jacked up, a deeper cut-off wall had been provided, and no further trouble had been experienced.

In view of the wide experience of the Ambursen Company in constructing hollow dams of reinforced concrete, the speaker strongly advised the Paper Company: (1) to engage the Ambursen Company to design the proposed dam; and (2), in case this Company should not get the contract for building the dam, to employ one of its experienced engineers or superintendents to be constantly on the ground while the dam was being built, in order to insure that the plans of the Ambursen Company would be properly carried out.

These recommendations were adopted by the Paper Company, and the speaker's connection with the Stony River Dam then terminated. The speaker had never seen the plans finally adopted, until after the partial failure of the dam in January, 1914.

* *Engineering News*, September 5th, 1912.

† *Engineering News*, April 1st, 1909.

Mr. Wegmann.

It appears that the westerly half of the dam was constructed by the Webber Construction Company, the lowest bidder, and the easterly half was built by the Ambursen Hydraulic Construction Company. According to the plans shown to the speaker by the Paper Company, after the partial failure of the dam, and according to various published accounts, the cut-off wall was only 5 ft. deep below the floor of the dam from the west end to Buttress 15, although the depth of water at the latter point was more than 25 ft. This part of the core-wall was founded on what appeared to be hard-pan, a tough clay which was very hard to pick but became soft after being under water. For the remaining length, the cut-off wall was carried down to what was thought to be bed-rock. As the usual rule is to make the depth of the cut-off wall at least half the depth of the water, the inconsistency of the manner in which the dam was constructed was apparent, and it is difficult to understand how the engineers in charge of the work could have been satisfied with such a shallow cut-off wall, especially as sheet-piling had been omitted at the ends of the dam, although they knew that there were porous seams in the clay formation.

After the partial failure occurred, the Ambursen Company issued a bulletin about "The Facts as to the Blow-out under the Stony River Dam at Dobbin, West Virginia." In this pamphlet the Company stated that the plans submitted to them by the speaker "showed sheet-piling under each edge as a cut-off", but that its Mr. Ambursen, after visiting the site of the dam, "expressed disbelief as to the possibility of driving sheet-piling, and recommended a cut-off trench to be carried down into sound material." The pamphlet continued as follows: "The test pits were at that time* examined jointly by the owner's engineer, their consulting engineer, Mr. Wegmann, and Mr. Ambursen."

The speaker cannot understand how this statement got into the pamphlet, as it is absolutely incorrect. He never met Mr. Ambursen and Mr. Bloss at the site of the dam, and, at the time mentioned, had no connection with the work.

A few days after the dam had been ruptured, Mr. A. G. Hillberg, representing the *Engineering Record,* visited the site. According to the published account of his observations,† the core-wall had only been carried down 5 ft. below the flooring of the dam, at the point where the break occurred, although the depth of the water in the reservoir at this point was more than 25 ft. Mr. Hillberg found, at the point of rupture, a "pervious seam of coal and sand with some clay as a binder, about 8 in. below the level at which the cut-off wall had been stopped." The seam was from ¼ to 6 in. thick, and about 4 ft. wide. This discovery gave a clear proof of the cause of the

* April, 1912.

† *Engineering Record,* January 24th, 1914.

Mr. Wegmann.

failure of the dam, and as Mr. Scheidenhelm, also, has stated in his report to the Public Service Commission of West Virginia that "failure was caused by the undermining of the over-burden or soil under the up-stream cut-off wall", the speaker thinks that this question might be considered as definitely settled.

Mr. Scheidenhelm has not only repaired the breach in the dam, but has made a number of important changes in its design and construction which the speaker will discuss.

Increasing the Spillway.—As originally built, the spillway was only 150 ft. long, and 3 ft. deep below the crest of the main dam. In case of a severe freshet, the whole dam could have acted safely as a spillway, if a suitable apron had been constructed on the down-stream side.

Assuming the probable maximum freshet at 1 386 sec-ft. per sq. mile—the figure given by the author for Cane Creek—the bulkhead section of the dam, as originally built, would have had to pass a sheet of water about 2.5 ft. deep. In all probability, the dam would have been able to pass this water, but, as no apron had been provided for the bulkhead section, the latter would have been gradually undermined.

In reconstructing the dam, Mr. Scheidenhelm increased the spillway capacity to about 1 840 sec-ft. per sq. mile. Although this may seem unusually large, it made the dam very safe.

Increasing the Storage Capacity of the Reservoir.—By placing flash-boards on the two spillways provided in the reconstructed dam, Mr. Scheidenhelm raised the water level 3.5 ft., and thus increased the reliable storage capacity of the reservoir by 25 per cent.

Resistance to Sliding.—The author made some experiments on the frictional resistance of clay moving on clay, shale on shale, and concrete on shale. In all these experiments, the coefficient of friction appears to have been determined for materials in motion. The force required to start the motion is known to be much greater than that needed to keep a body moving. As sufficient data on these points are not yet available, the author acted wisely in adopting conservative figures.

The original dam had withstood successfully for about 65 days the pressure due to a full reservoir, before failure occurred on January 15th, 1915, and there was no indication that the dam had not sufficient stability against sliding. As the weepers in the floor of the dam had, doubtless, been closed by ice during this period, and as the reservoir had not, at that time, been made water-tight by silting up, the dam, in all probability, had been subjected to upward pressure.

Resistance to Overturning.—One of the advantages of a hollow dam of reinforced concrete, having its deck on an angle of 45°, is its stability against overturning. As the water rose in the reservoir and finally over-topped the crest of the dam, the line of pressure was

Mr. Wegmann.

first drawn up stream and then down stream, and intersected the base of the dam near its center when the water reached the highest flood level. The speaker thinks the original dam would not have failed by overturning. The provisions made during the reconstruction to increase the stability against sliding, at the same time, gave the dam a still larger factor of safety against overturning.

Extension of the Cut-Off Wall.—Mr. Scheidenhelm has extended the shallow cut-off wall near the west end of the dam to rock. His explorations by test pits and drill-holes showed that, in some places, where the cut-off was thought to have been founded on rock, it was really built on boulders, and permitted leakage under its base. In such cases, Mr. Scheidenhelm carried the cut-off deeper, and, in other places, he made, by a small V-shaped trench filled with concrete, a water-tight seal between the up-stream side of the cut-off wall and the bed-rock. The width of this wall—only 2½ ft.—did not seem to be sufficient for the maximum pressure it had to sustain, and, therefore, it is not surprising that Mr. Scheidenhelm found that in some places water leaked through the cut-off wall.

Miscellaneous Construction.—Mr. Scheidenhelm has strengthened the original footings of the buttresses, remedying faulty conditions in places by pressure grouting. He has also provided a proper drainage system for taking care of the leakage through the foundation soil, and has housed in the higher bulkhead portions of the original dam by curtain-walls and roofs, in order to prevent serious freezing in the drainage system, etc.

In conclusion, the speaker compliments the author on the very thorough manner in which he has repaired and improved the dam, and on the detailed account of this work which he has given in his valuable paper.

Mr. Church.

IRVING P. CHURCH,* ASSOC. AM. SOC. C. E. (by letter).—In connection with Fig. 12, of his valuable and exhaustive paper, the author refers to a tentative process by which such a curve as *a-b-g*, or "Discharge over Spillways", is determined; that is, a curve showing the rate of discharge, Q, over the spillway as a function of the time; so that with Q known as a function of H, the depth on the spillway, it becomes possible to compute H for any epoch; this being a case where the rate of influx into the reservoir, or "flood discharge", is given as a function of time, in such a curve as *a-c-d*, or graph of flood discharge, in Fig. 12.

As a matter of this kind is very rarely treated in books on hydraulics, it may be of interest to consider the strict mathematical nature of such a problem, that is, where efflux takes place through an orifice or over a spillway from a very wide vessel or reservoir, simultaneously

* Ithaca, N. Y.

with an influx into the reservoir; and where it is desired to determine the value of the head, H (head on orifice or over crest of spillway), as a function of the time, t. Mr. Church.

At any instant of time, suppose the surface of the water in the reservoir to be rising, and assume the following notation:

A = the area of that surface, at any instant;
F = area of orifice, if one is used;
μ = coefficient of discharge of orifice;

and, if a spillway is used, let

b = length of crest; and
c = coefficient of discharge.

Also, let

Q = rate of efflux, in cubic feet per second, at any instant;
and Q' = rate of influx, in cubic feet per second, at any instant.

During any short interval of time, $d\,t$ (time-increment), H increases by $d\,H$, and the gain of the volume of water in the reservoir must be equal to the excess of influx over efflux during this time; that is,

$$Q' \,.\, d\,t - Q \,.\, d\,t = A \,.\, d\,H \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

(If the surface were sinking, we would have $-A \,.\, d\,H$ instead of $+A \,.\, d\,H$.)

Case I.—Let Q' be constant and the reservoir have vertical sides, with efflux taking place through an orifice; then A is constant. Let H_0 be the initial value of H, and let the constant, Q', be written in the form, $Q' = \mu\, F \sqrt{2\,g} \,.\, K^{\frac{1}{2}}$, where K is an ideal constant head, easily computed. Equation (1) now becomes:

$$d\,t = \frac{A}{\mu\, F \sqrt{2\,g}} \,.\, \frac{d\,H}{K^{\frac{1}{2}} - H^{\frac{1}{2}}} \ldots\ldots\ldots\ldots\ldots (2)$$

This is readily integrable by a temporary change of variable, $K^{\frac{1}{2}} - H^{\frac{1}{2}}$ being denoted by Z; so that $d\,H = -2\,H^{\frac{1}{2}} \,.\, d\,Z, = 2\,(Z - K^{\frac{1}{2}}) \,.\, d\,Z$.

Now, $H = H_0$ for $t =$ zero and, finally, after integration, the form is obtained,

$$t = \frac{2\,A}{\mu\, F \sqrt{2\,g}} \left[\sqrt{H_0} - \sqrt{H} + \sqrt{K} \,.\, \log_e \left(\frac{\sqrt{K} - \sqrt{H_0}}{\sqrt{K} - \sqrt{H}} \right) \right].$$

giving the time, t, as a function of H. If t is given and H sought, resort must be had to solution by trial. (By "$\log_e$" is meant Naperian logarithm.)

Case II.—Let the reservoir have a rectangular spillway on which initially (that is, for $t =$ zero), the head is H_0 though at any later instant it is H, the rate of efflux being then $Q = c \,.\, b \sqrt{2\,g} \,.\, H^{\frac{3}{2}}$. Let the

Mr. Church.

rate of influx, Q', be constant, and let an expression be written for it in the form, $Q' = c \cdot b \sqrt{2g} \cdot K^{\frac{3}{2}}$, where K is an ideal constant head. The sides of the reservoir are vertical; hence A is a constant.

Assuming that Q' is greater than the initial value of Q, we have from Equation (1):

$$d\,t = \frac{A}{c \cdot b \sqrt{2g}} \cdot \frac{d\,H}{K^{\frac{3}{2}} - H^{\frac{3}{2}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

The integration* of this equation is quite roundabout, but finally† leads to the result

$$t = \frac{A}{3}\frac{K}{Q'}\left[\log_e \left(\frac{\left[\sqrt{K} - \sqrt{H_0}\right]^2 \left(H + \sqrt{H\,K} + K\right)}{\left[\sqrt{K} - \sqrt{H}\right]^2 \left(H_0 + \sqrt{H_0\,K} + K\right)}\right)\right.$$

$$\left. - \sqrt{12}\,\text{tan.}^{-1}\left(\frac{\left(\sqrt{H} - \sqrt{H_0}\right)\sqrt{12\,K}}{3\,K + \left(2\sqrt{H_0} + \sqrt{K}\right)\left(2\sqrt{H} + \sqrt{K}\right)}\right)\right]. \quad (5)$$

in which, as before, $\log_e$ signifies "Naperian logarithm of"; and tan.$^{-1}$ denotes "anti-tangent of", or "arc whose tangent is"; for example, tan.$^{-1}$ 0.488 = 0.454 (since tan. 26° = 0.488, and 26° expressed in arc ("radians") is 0.454).

Case III.—Rate of influx, Q', not constant, but proportional to the time. Efflux over a spillway. If Q' is a linear function of t, that is, is proportional to t, when t is reckoned from a special origin, we have a case that is suggested by the graph of the Cane Creek flood of the author's Fig. 12; since this curve, *a-c-d*, etc., may be considered to be made up of a number of consecutive straight lines. Among the more prominent of these straight lines is the portion, *c-d*; and this portion has been treated by the writer in the attempt to discover the law connecting the variables, H and t, holding good for any instant of time between about 9.30 and 10.30 A. M.

If a straight-edge be applied to the diagram in Fig. 12, it will be found that the prolongation of the straight line, *d-c*, cuts the time-axis very closely at 9 A. M.; and that the point, *d*, corresponds to a value of $Q' = 5\,000$ cu. ft. per sec. at 10.30 A. M., that is, 5 400 sec. along the time-axis from 9 A. M. Hence, if we reckon t from 9 A. M., we have the proportion, Q': 5 000:: t: 5 400, or $Q' = 0.926t$ (for the foot and second as units).

Since the elevation of the surface of the water at this stage of the flow is less than 140 ft., only two of the three spillways will be in action, namely, the "old" and the "new"; and these have the same

* Detail will be found on p. 200 of Frizell's "Water Power", First Edition.

† On pp. 362 and 430 of *Engineering News*, November and December, 1901, will be found interesting matter relative to this, by the Messrs. Gould.

crest elevation of 136.0 ft. and hence are equivalent to a single spillway for which the rate of discharge, or "capacity" (see Fig. 11), is Mr. Church.

$$Q = 3.65\ (150 + 133)\ .\ H^{\frac{3}{2}};$$

that is,

$$Q = 1\ 033\ .\ H^{\frac{3}{2}} \text{ cu. ft. per sec. (with } H \text{ in feet).}$$

Again, in Fig. 10, it is to be noted that the curve of reservoir capacity is nearly straight between Elevations 134.0 and 138.0, the gain of volume in that interval of 4 ft. being 500 000 000 gal. or a fairly constant rise of 125 000 000 gal. per ft. Division by 7.58, and by 1 ft., gives 16 710 000 sq. ft.* as a fair estimate of the area, A, in the region of Elevation 136.0. These expressions and values having been inserted in Equation (1), there is obtained, after reduction and division (for foot-second units),

$$10\ 000\ 000\ \frac{d\,H}{d\,t} = 0.554\ t\ -\ 618.4\ H^{\frac{3}{2}} \ldots\ldots\ldots\ldots (6)$$

This differential equation not admitting of a strict mathematical solution,† resort was had to plotting a curve with H as ordinate and t as abscissa (t is reckoned from 9 A. M. and H is the head on the spillway), a special method being used for the purpose, giving a very close approximation.

It is a property of a circular arc that the tangent lines drawn at its extremities intersect at a point equi-distant from the points of tangency, and the method in question consists virtually in drawing, "tandem", a number of very flat circular arcs, the radius of each being the average radius of curvature for the small extent of curve involved. The arcs themselves are not drawn, being sufficiently defined by the extremities and their tangents.

For each of the five values of H: 0.6, 0.7, 0.8, 0.9, and 1.0 ft., the value of the derivative, $\frac{d\,H}{d\,t}$, was computed from Equation (6) for each of some six or eight values of t, chosen so that, by previous inspection, the true value of t for the assumed H would probably lie within the range taken; and these thirty or forty values were tabulated.

In Fig. 37, for the starting point, D (corresponding as regards time to points, b and c of the author's Fig. 12), we have H = 0.50 ft., and t will be taken as 2 034 sec. (that is, from 9 A. M.; see Fig. 12). Also, the value of the "slope" of the tangent line at D, namely, $\frac{d\,H}{d\,t}$, is found from Equation (6) to be $\frac{0.0910}{1\ 000}$. A straight line, $D\,F$, is then

* From the curve "area in acres" of Fig. 10, we might also have taken $A = 386$ acres $\times\ 43\ 560 = 16\ 820\ 000$ sq. ft.

† Information on this point was kindly furnished by James McMahon, Professor of Mathematics, Cornell University.

Mr. Church.

drawn through D at such an angle that a portion having 1 000 sec. as horizontal projection has 0.0910 ft. as vertical projection. Use was made of co-ordinate paper with twenty divisions to the inch, and the scales adopted were 1 000 sec. to 5 in. horizontally, and 0.10 ft. to 2.5 in. vertically.

A point, E, is then found by trial on the horizontal line, GE, that is, for $H = 0.60$ ft., such that for the value of t for this point, E, the straight line drawn through E and having a slope, $\frac{d\,H}{d\,t}$, obtained from Equation (6) for these values of H and t, intersects the previous tangent line, DF, in a point, F', making $\overline{F'D}$ equal to $\overline{F'E}$. We have thus determined very closely a new point, E, of our curve and the tangent line, $F'\,EJ$, at this point. A similar procedure, involving the tangent, $E\,J$, and the horizontal line for $H = 0.7$ ft., gives another point on the curve and also its tangent line; and so on.

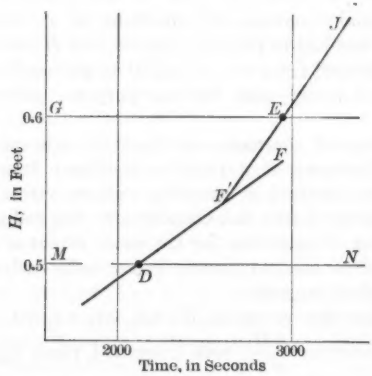

FIG. 37.

The five points thus obtained in addition to the starting point, D, are plotted in Fig. 38 and give the curve there shown. The figures annexed to the points give the abscissas (time), in seconds.

Investigations involving a change of origin and the plotting of the logarithms of the new co-ordinates, brought out the fact that the relation

$$H = 0.30 + \left(\frac{0.025}{10\,000\,000}\right)(2\,000 + t)^{2.19} \quad \ldots\ldots\ldots (7)$$

is practically the equation to this curve, within the limits shown; giving results not more than 1% in error when H is solved for. The t of this equation is reckoned from 9 A. M., as before.

Mr. Church.

For the point, *d*, in the author's Fig. 12, the value of t is 5 400 sec. and this value, in Equation (7), gives $H = 1.04$ ft. For this point the author has 137.0 ft. as elevation of the surface; that is, $H =$ just 1.00 ft.; and, under the circumstances, this may be considered a very fair agreement of the two methods.

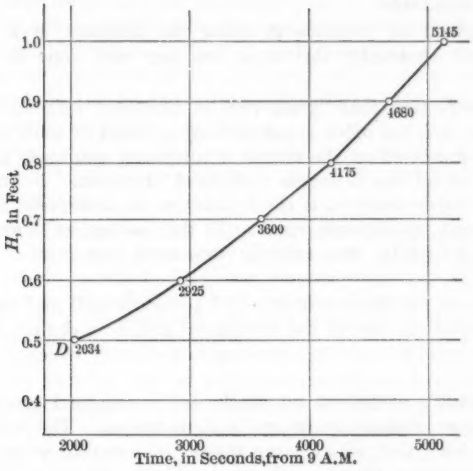

FIG. 38.

Mr. O'Shaughnessy.

M. M. O'SHAUGHNESSY,* M. AM. SOC. C. E. (by letter).—The author is to be commended for the thorough manner in which the reconstruction of this dam was undertaken. The complete way in which the details of the construction and the reasons therefor have been described are also worthy of commendation.

To a Western engineer, the extraordinary flood flow per square mile, of the region which drains into the dam, appears to be alarming. It would seem that the new spillway capacity, more than six times the original size, should surely be ample to underwrite the structure against flood damage in the future. It would also seem that this hollow, reinforced concrete type of dam was well adapted for this particular site, and that its original failure was due, not to the type of structure, but, in a large way, to lack of adequate care with the foundation portion of the work. Neglect of this nature is likely to cripple any dam, and one of this type perhaps less than any other, as a fracture of a couple of panels will release the stored waters and safeguard the rest of the structure.

* San Francisco, Cal.

Mr. O'Shaughnessy.

One of the cardinal principles to be observed in any dam foundation is to remove the uplift pressure and make a perfect contact between the water-tight skin or face of the dam and the solid reliable foundation material. The results of tests on the friction resistance of clay soil and the analysis of the sliding factors furnish data of original labor, which are creditable.

The method of pressure grouting the footings is a matter of interest, and apparently this work was very well done in the reconstruction.

The observation that "great care is necessary even in foundation work, where it is too often assumed that any kind of work will suffice", should be impressed on the minds of all young engineers as the most important of all the elements that need attention. No matter how perfect the superstructure, if the foundation is inadequate, final failure or consequent trouble will result. If the leakage on May 25th, and November 1st, 1915, was actually measured, the facts would be of interest.

The reason for the construction of a curtain-wall and roof to avert the freezing of the top of the weep-holes and deep drains, is a matter of much interest to engineers working in a country which is practically frostless.

The author's comments on cracks in the original structure from lack of proper contraction joints is illuminating. The writer's experience has been that where large masses of concrete were exposed to rapid temperature changes, there should be joints at least 40 ft. apart, and, in ditch lining, he has used joints as close as 12 ft. to advantage.

With reference to asphalt in expansion joints, there is a tendency of this material to flow in hot weather. Such a condition was studied in the reconstruction of the Twin Peaks Reservoir, in 1912, and by adding a percentage (17½% by weight) of diatomaceous, kieselguhr, or infusorial (different names for the same substance, which is almost pure silica), to the asphalt, this tendency to flow was removed, and the asphalt still retained its plastic condition.

In stating the cost per cubic yard, the details of the cement and iron costs are missing, and would be interesting if added by the author.

The writer has seen no paper, for some time, which has been so candid in every manner in describing all the engineering features, so that brother engineers can profit by the experiments and experience gained in this structure.

Mr. Justin.

JOEL D. JUSTIN,* M. AM. SOC. C. E. (by letter).—This paper teaches a much needed lesson; a lesson not so much needed by the Engineering Profession as by the promoters and owners of projects in connection with which the construction of dams is a feature.

* Chippewa Falls, Wis.

Mr. Justin.

If an owner is considering the advisability of constructing a dam, there is one way of no regrets for him to go about the inception of such a project. If he is not already in contact with engineers versed in that particular line of work, he can readily meet them through other owners who have built dams. Having chosen his consulting engineer, the owner should authorize him to make a complete preliminary report on the project, including the economic features. The extent of such preliminary report and investigation should be left largely to the judgment of the engineer, just as the number of visits that a doctor makes his patient should be left to the judgment of the doctor, and not to that of the patient.

Of course, such an engineer should have nothing to sell except service. If the preliminary report is favorable, this ideal owner will say to the engineer:

"Very well, then, we will build this structure as you recommend, and you will consider yourself retained to design the dam and appurtenant work, and to supervise the construction. We will expect you to have on the ground at all times competent assistants to see that your orders are executed. In this matter, Mr. Engineer, we put ourselves entirely in your hands."

It is true that the best of engineers sometimes make mistakes. So do doctors and lawyers. The difference is that the two last named professions have an excellent opportunity of "getting away with it", whereas the mistakes of the engineer stare the whole world in the face, for they can be seen and photographed. It is probably for this reason that the business man, who accepts as infallible the advice of his lawyer or doctor, questions and often ignores the advice of his engineer. It is certain, however, that if a larger proportion of owners were to follow the course of action just outlined, there would be fewer failures charged to the Engineering Profession.

In the case of the Stony River Dam, a competent consulting engineer was retained, apparently merely to investigate the feasibility of the site. His connection with the project ceased when the contract for the construction was let, and he apparently had nothing to do with the design. Had he also been retained to design and supervise the construction of the dam, it is improbable that Mr. Scheidenhelm would now be writing about its reconstruction.

Hollow dams of the type used at Stony River have manifest advantages over other types for the conditions existing at the chosen site. In many such dams insufficient attention has been given to foundation problems. It would almost appear that it has been quite customary to use what may be designated as stock designs, without much regard for local conditions, and without very thorough sub-surface investigations.

Mr. Justin.

The paper proves that the author went into this matter in a most thorough and complete manner. He realized that a reconstruction of this nature required as much if not more engineering investigation than an entirely new project. In spite of his convincing hydrological study, Mr. Scheidenhelm's provision for a spillway capacity of 1 840 sec-ft. per sq. mile seems rather high. Much of this, it is true, is obtained by merely allowing spilling over the bulkhead section or "Intermediate Spillway." It appears probable, from the author's study, that the duration of a flood when the capacity of the original spillway would be exceeded would be brief. Consequently, it would seem that the author might have saved the cost of the down-stream apron on the new spillway. The abutments at the east and west ends of the masonry structure might have been raised several feet to prevent water flowing over the earth, and then, when the capacity of the old spillway section was exceeded, discharge would take place over practically the entire width of the dam. It would have been necessary, of course, to extend the tumbling hearth for the entire distance. It would probably also have been desirable to provide an additional apron to protect the soil just down stream from the dam.

The author shows most conclusively that the resistance to sliding of the structure as originally built was insufficient. This condition is no doubt quite often the case with existing hollow reinforced concrete dams built on soil foundations. In the design of such structures there has often been far too little attention given to making adequate provision against sliding. The methods adopted by the author for increasing the resistance to sliding are most ingenious and effective. At the same time their execution must have been expensive.

After investigation the author decided that the safe soil pressure had already been reached, and therefore he did not consider it safe to obtain the desired additional resistance to sliding by filling in with earth on the floor of the dam. This objection might have been overcome by extending the reinforced concrete floor or footings down stream from the buttresses until the desired maximum soil pressure was attained. To take the reaction from the soil pressure it would have been necessary to cantilever the buttresses out in a down-stream direction over the additional floor or apron. This cantilever would probably take the form of a triangular addition to the buttresses at their down-stream ends. The earth filling, to produce the necessary weight, would be placed inside the dam, and the bulk of it as far up stream as possible, thus obtaining a lower maximum soil pressure per unit of area at the toe than if the fill were evenly distributed.

The two problems of securing proper resistance to sliding and adequate cut-off should be handled as one, and this the author has

done. The construction of the cantilever heel, the underpinning, and the extension of the original cut-off were clearly very expensive. This work, aside from the mere grouting of leaky joints and of voids along the cut-off, would be omitted in the method the writer has in mind. In the case of a dam on a soil foundation, the construction of an impervious cut-off to rock is frequently out of the question. The problem is more generally one of introducing sufficient frictional resistance to the flow of water under the dam, so that the velocity of the water issuing from the down-stream toe is insufficient to move the foundation soil. In fact, the desirability, in the case of a yielding soil, of a deep cut-off at the heel to rock is open to question, as it produces a tendency to increase the maximum soil pressure at the toe. The necessary frictional resistance to the flow of water under the

Mr. Justin.

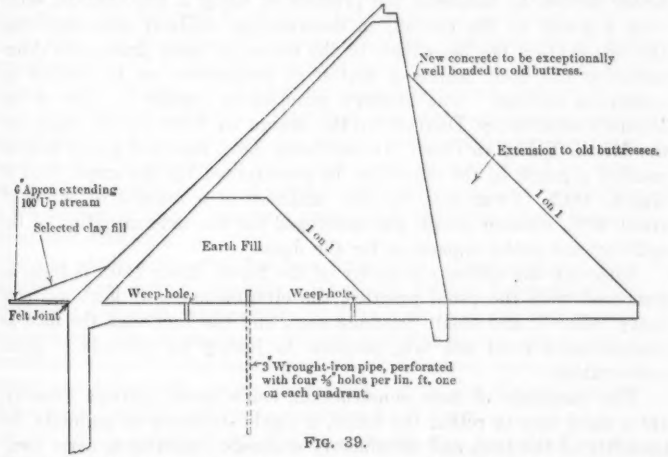

FIG. 39.

dam is obtained by increasing the distance through which the water must flow before it can escape at the down-stream toe. This may be obtained by (1) increasing the depth of the cut-off, (2) by increasing the width of the base, (3) by a combination of these two methods.

The additional down-stream floor or apron, suggested by the writer as a method of obtaining decreased soil pressure, would, by increasing the frictional resistance, decrease the velocity of the water flowing through the soil. This, however, would probably not be sufficient. Therefore, the writer would use an up-stream apron. The thickness of this layer need be only 6 in. or indeed it might consist of a few layers of "Gunite" on a light-mesh reinforcement, there being slight stresses to be resisted. For the typical section, the width of this apron should probably be about 100 ft., as it would not be wise to

Mr. Justin. place great dependence on the original cut-off. At the junction of the apron and the heel there should be a special flexible joint which would remain tight even if there should be a slight movement in the dam. A small fill of selected clay should also be placed at this point. The alternative for providing against seepage and sliding here suggested is shown in Fig. 39, the dimensions being merely illustrative.

In outlining this method of increasing the resistance to sliding and to seepage, the writer realizes that it was doubtless considered by Mr. Scheidenhelm. The only reason for suggesting it is, that, from the author's description, it would appear that it would have been cheaper than the equally efficacious one adopted.

Mr. Riegel. Ross M. Riegel,* Assoc. M. Am. Soc. C. E. (by letter).—The writer desires to commend the practice of using a hypothetical storm with a graph of the run-off, in determining spillway characteristics. His observation has been that, in the design of most dams, this determination has been largely a matter of conjecture, as is attested by numerous failures. The author's practice is similar to that of the Miami Conservancy District in the design of flood-control dams for the Miami Valley in Ohio. In the latter case, recorded gauge heights enabled a graph of the run-off to be constructed for the great flood of March, 1913. From this, by the addition of a margin of safety of about 40%, another graph was developed for the determination of the spillway and outlet capacities for the dams.

Although the spillway capacity of the Stony River Dam is high, as compared with the usual practice, the circumstances of high altitude, heavy rainfall, and small drainage area, and the fact that the dam as reconstructed must not fail, combine to justify an attitude of great conservatism.

The essentials of dam construction, aside from spillway capacity, are a tight face to retain the water, a stable structure to maintain the integrity of the face, and satisfactory drainage facilities to carry away any water which may pass the face or the foundation. In all these essentials the original dam appears to have been deficient. The tight face was wanting by reason of an insufficient and faulty cut-off; the drainage provision was such that it was subject to interference by freezing during a great part of the year; and the resistance to sliding seems to have been markedly deficient.

In the reconstruction, these faults have been remedied with a degree of thoroughness not often seen. The improvements at the heel, as well as the various extensions and underpinning of the cut-off, have corrected the faults in the original face. In his discussion, Mr. Rutenberg seems to have overlooked this point entirely. Had nothing been done to improve the cut-off, the drainage provisions of the recon-

* Dayton, Ohio.

structed dam might indeed have been insufficient, and Mr. Rutenberg's points would have been well taken. The fact that such leakage as did occur after the dam was refilled was readily checked, or checked itself after a short time, is ample testimony to the effectiveness of the measures taken. Mr. Riegel.

The provision made to protect the drainage outlets from freezing, namely, housing in the base of the dam, savors of the heroic, but seems to be justifiable. The author was repairing an existing structure, and to have developed an ideal system of sub-drainage with protected outlets below the dam was evidently prohibitive as to cost. Under the system adopted, any seepage water will find its readiest avenue of escape through the weep-holes or pipes. Its escape immediately under the footing will be practically prevented by the new "toe" wall. Moreover, after passing the improved cut-off, the motion of seepage water through any strata below this wall will be so slow that no erosion need be feared.

The provision of increased resistance against sliding seems to have been necessary and to have been well worked out. The writer fails to see any better method of remedying this defect, and feels that the device is worthy of imitation. Although the criticism has been made that the heel- and toe-walls are too light to carry the entire horizontal thrust, it seems to the writer that such a requirement would be excessive. Their function is to add to the resistance normally offered along the top surface of the foundation itself, and, therefore, their strength is doubtless sufficient.

On the whole, the writer has been impressed by the care and thoroughness of the author's methods. He wholly fails to comprehend Mr. Rutenberg's criticism, which seems to have been based on rather hasty consideration. For instance, his remark that the dam is less safe now than before reconstruction seems particularly unsound, inasmuch as the original dam failed after being in ordinary service for 65 days, and the reconstructed one has now been in service for 2 years.

F. W. SCHEIDENHELM,* M. AM. SOC. C. E. (by letter).—The discussion of the paper has been very interesting to the writer, as presumably it has also been to other engineers concerned with the problems treated. Among other things, it serves to emphasize the fact that there is rarely agreement among engineers as to the exact measure, or margin, of safety which should be given to, or is possessed by, a structure. On the whole, the writer finds much cause for satisfaction in the comments contained in the discussions. Mr. Scheidenhelm.

Frequently, papers presented before the Society and the discussions thereon result in a symposium of data and opinion on certain subjects. Such is the case with regard, in particular, to two problems which were involved in the reconstruction of the Stony River Dam, and are treated in the paper.

* New York City.

Mr. Scheidenhelm.

The first of these problems concerns the determination of the maximum flood for which spillway capacity is to be provided, and the consequent determination and design of the spillway provision itself. Of the ten members who have discussed this matter, only one, Mr. Gregory, feels that the writer has "surely gone beyond the necessary limit." The great majority, however, apparently agree on the proposition that a drainage area as small as that of Stony River at the dam site requires entirely different treatment than do larger areas, and that the exceptionally large maximum run-off adopted, although surprising, is warranted.

Referring to the comment of Mr. Gregory (page 1060) the writer feels that it is certainly necessary to take into account, not merely rainfalls of 2 or 3 hours' duration, but those of considerably longer periods, and more especially their consequent floods. This is for the reason that from such rainfalls the run-off (into the reservoir) which immediately precedes the maximum or critical periods of, say, 2 or 3 hours, necessarily affects the absorption or equalization capacity of the reservoir during the vital period.

It is true, as pointed out in the paper, that a record or graph of run-off never truly represents the corresponding rainfall; that is, the maximum rate of run-off is always less than the maximum intensity of rainfall. Yet, even making full allowance for this fact, as applied to actual Stony River conditions, it is reasonably evident, from the studies depicted in Figs. 12 and 13, that the length of the period of rainfall which should be considered is at least 6 hours; and it must be remembered that rainfall does not persist at a uniform intensity through any 24-hour period. Thus, were there an automatic gauge record available for the 22-in. rainfall during 24 hours at Altapass, N. C., on June 15th-16th, 1916 (page 930), the record for the maximum 6 hours would probably be astounding.

Again, looking at the matter from Mr. Gregory's point of view, and making the reasonable assumption, size and topography of drainage area considered, that "the peak of the run-off at the dam is equal to the greatest average rate of rainfall during any 45-min. period" (page 940), it is to be noted from Fig. 15 that "the most severe run-off conditions reasonably conceivable", there shown, indicate a rainfall with an intensity averaging only about 4 in. per hour for the maximum 45 min. This intensity is somewhat less than that given for the same period by the Talbot formula, quoted by Mr. Gregory, and, of course, is less, by an even greater amount, than the corresponding "Maximum for Greater New York" (Fig. 32). Incidentally, the Talbot and the Greater New York curves of Fig. 32, when plotted on Fig. 9, fall outside of the group of curves shown thereon; in other words, the curves of Fig. 32 show the greater intensities of rainfall.

Mr. Scheidenhelm.

It is interesting to note that apparently the Cane Creek and Elkhorn Creek floods, which formed the basis for the studies presented in the paper (page 926) were of such intensity as not to be included within the formula proposed by Weston E. Fuller, M. Am. Soc. C. E.* The same is true also of a run-off of 1 302 cu. ft. per sq. mile, reported† for the drainage area of 143 sq. miles of Devil's Creek, near Viele, Iowa.

The method of determining or checking spillway capacity by means of graphs of hypothetical maximum floods to be provided against, seems to meet with approval. Similar methods are shown to have been used in the design work of the Miami Conservancy District at Dayton, Ohio, as referred to by Mr. Riegel (page 1086), and discussed in considerable detail by Mr. Grant (page 1067). A remarkably close agreement of results is evident from comparison of Figs. 12 and 36, the former being based on the method used by the writer, whereas the latter is based on the flood routing method applied on the work of the Miami Conservancy District.

The second feature provoking considerable discussion is the utilization of the underlying foundation soil in setting up resistance to sliding. On this subject the discussion of Professor Cain is a contribution of exceptional value.

One may fairly question whether present experimental information regarding the behavior of soils is sufficient to warrant the acceptance of Professor Cain's application of Coulomb's laws to cases, such as that of the Stony River Dam, where there is involved the question of sliding, and more particularly of impending sliding. In fact, the writer still feels constrained to distinguish between the conditions existing before a body of clay has failed in shear along a given plane or surface and the conditions existing after the resistance to shear has been overcome (that is, when, in his terminology, cohesion has given way to friction, plus any adhesion). Such distinction does not appear to be inconsistent with Coulomb's laws, especially as expressed by Professor Cain somewhat more broadly in his paper on "Cohesion in Earth."‡ In fact, Professor Cain's more frequent use of the term "shear" in his analyses based on Coulomb's laws, as applied in his discussion (page 1045), is significant. Even Professor Cain now considers that possibly not all "cohesion" (Cain) is destroyed on the beginning of the actual motion or sliding.§

However that may be, all must be in full agreement with Professor Cain in his emphasis of the "need for comprehensive experimentation

* Flood Flows," *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 564.

† *Water Supply Paper No. 162*, U. S. Geological Survey.

‡ *Transactions*, Am. Soc. C. E., Vol. LXXX, p. 1316.

§ This appreciable part of "cohesion" everted in addition to friction during the actual sliding of clay on clay (p. 1045), the writer would term "adhesion", as more accurately describing its nature.

Mr. Scheidenhelm.

to determine the coefficients of cohesion." Moreover, the writer believes that Professor Cain has performed an important service in presenting in such detail the several analyses of the Stony River problem on the basis of coherent earth. It is not improbable that, as the result of such work as is now being carried on by the Society's Special Committee on Soils, the treatment advanced by Professor Cain may be adopted, at least in part, and especially as applied to cases of actual sliding.

The writer agrees entirely with Professor Cain that probably the effect of a longer time of application of a given shearing load on a body of clay under test would be to afford lower values of unit shearing resistance (page 1046). It should be noted, however, that, in the Stony River design, no reliance was placed on the shearing resistance of the foundation soil.

In the interesting analyses (pages 1046-48) of the original structure before failure, based on the theory of coherent earth, Professor Cain unwittingly made several erroneous assumptions.

The mistake apparently was caused by his treatment of the section of dam shown on Plate XII as being taken at the maximum height portion of the dam. This is not the case, for Plate XII shows the "Typical Section at Bay 35" referred to in Columns (3), (5), (7), and (9) of Table 3. The resulting error in the value of Q, as derived by Professor Cain (page 1047), is not serious, but, unfortunately, the same mistake made later in his discussion robs the results of their significance, though, of course, it does not deprive the theoretical analysis of its value as such.

Thus, in assuming anchoring walls applied to the original structure, as shown on Plate XII, Bay 35, Professor Cain perforce used loads (page 1048) as given in the writer's Cases I and II (pages 956-958) and applying to the sections of maximum height, instead of to the section at Bay 35. The difference in height of sections will be apparent on reference to Plate IX. Moreover, the loads used by Professor Cain apply to the structure in its original condition, whereas both concrete and water weights were greatly increased in the reconstruction, without any increase in the horizontal water thrust (Table 3). The horizontal water thrust for Case I, for instance, is but 53 820 lb. per lin. ft., instead of 81 000 lb., as assumed by Professor Cain.

In consequence, the conclusions as to resistance to sliding, furnished under the respective hypotheses set up under the theory of coherent earth, are not applicable. The corrected figures show much larger margins of safety. Nevertheless, it appears to the writer that the appropriateness of the methods used by Professor Cain has in no wise been affected; and, for the purpose of theoretical study, those interested may well disregard the inapplicability of the figures.

Mr. Scheidenhelm.

Professor Cain neglects the resistance along *BC* and *IJ* of his Fig. 28, on the ground that there is "but little weight over parts of these surfaces" (page 1053). It should be evident, however, on study of Plate XII and the description of the toe-wall and its effect (page 964), that the new toe-wall in essence extends the base of the dam as far as *F* (Fig. 28), and that, in fact, the greatest vertical loads on the soil occur at the very down-stream edge of the toe-wall, namely, just to the left of the plane represented by the line, *FC*. For this reason the writer believes that one is not warranted in omitting from consideration the resistance along *BC* and *IJ*.

The graphical solution for the passive resistance of the down-stream foundation soil is exceedingly interesting, and here again those interested incur a debt to Professor Cain. The point made by him, that the writer was too conservative in assuming zero load at the free surface of the earth at *F* (Fig. 28), is well taken, as is evident from the analyses (pages 1057-58).

On the subject of the safety of the structure, as repaired and strengthened, the measures taken appear to have general approval, except by Mr. Rutenberg. In view of the nature of the discussion submitted by him (pages 1029-35), the writer is loath to make a detailed reply. However, a number of the premises adopted by him diverge so widely from the facts that it appears advisable to examine some of the points which he has raised, in order properly to co-ordinate the paper and the discussion thereof. Except in special instances, the writer will refrain from discussing mere expressions of opinion appearing in Mr. Rutenberg's contribution, for, of course, each engineer is entitled to his own opinion, and it would be futile to attempt to obtain agreement on all points:

1.—With reference to the discussion on remedying the faulty condition of the foundation soil (page 1030), the writer desires to emphasize that reliance against leakage was placed solely on the extension and perfecting of the cut-off wall, and not on the compacting of the foundation soil by grouting. The object of the grouting, as stated, it is believed clearly, on pages 987-988, was to compact the soil for bearing purposes. In other words, it was to remedy conditions caused by leakage which occurred prior to the failure of the dam; or, in the words of the desideratum expressed by Mr. Rutenberg himself, "to fill, if possible, all the holes found in the foundation soil" (page 1033). It will be noted that the subject of pressure grouting was treated by the writer primarily under the heading of "Footings", and not under that of "Leakage and Drainage."

In passing, it may not be out of place to remark that it is the writer's experience that pressure grouting in porous soils and gravels is not a sure means of causing water-tightness, but that, on the other hand, such grouting is generally effective in rock having pronounced seams.

Mr. Scheidenhelm.

2.—The writer agrees in essence with Mr. Rutenberg's statements in the last paragraph on page 1030, but cannot agree with his conclusion as expressed in the paragraph following. The writer must still insist that "the smaller the coefficient of frictional resistance, the less the net effect of uplift pressure." Perhaps this anomaly of agreement on certain premises and disagreement as to the conclusion is explicable on the ground that Mr. Rutenberg has not noted that the writer's statement applies solely to the effect of uplift pressure in so far as resistance to sliding is concerned. This is manifest from the context (page 947).

The meaning of the writer's statement can perhaps be made more clear by using a numerical example. Thus, if over a given area of base of dam there should exist an uplift pressure of 100 000 lb., there would result the equivalent of a net reduction in weight by the same amount. The net reduction in weight, however, is a different thing from reduction in resistance to sliding. For instance, if in this hypothetical case the coefficient of frictional resistance were 0.75, the resistance to sliding would, by reason of the assumed uplift, be decreased by 75 000 lb. In the case of the Stony River foundation soil, however, the coefficient of frictional resistance probably averages about 0.33. This coefficient, applied to the uplift condition just assumed, would result in decreasing the resistance to sliding by only 33 000 lb.

3.—The expression of opinion that leakage and percolation in the dam should have been intercepted "directly and immediately on the up-stream face of its cut-off wall, and discharged down stream by special channels without any pressure" (page 1031) is so unique and, in the writer's opinion, illogical, that he hesitates to believe that it was intended to make such a statement. The writer insists that one need be concerned only with such water (leakage) as passes through the diaphragm (intended to be water-tight) of which the cut-off wall is a part. Of course, the primary effort was devoted to making the cut-off wall as tight as possible. In this regard, the results of the reconstruction speak for themselves, namely, that at present the merest trickles of water pass through or under those portions of the dam founded on earth over-burden.

4.—Although desiring to avoid useless quibbling over terms, it seems necessary to point out that the statement imputed to the writer, "that water under pressure in the foundation soil is never harmless" (page 1031), is not warranted by the statement that, in the case of the Stony River foundation, deep-lying pockets, if any, of water under pressure are "relatively harmless" (page 997). By "deep-lying pockets of water" the writer meant accumulations of water, under pressure, existing at elevations below the bottom of the new anchoring wall at the heel; in other words, below the probable location of the main "planes of least resistance." Such deep-lying pockets of water are relatively

harmless, partly because of their depth, and partly because of the comparatively small coefficient of frictional resistance obtaining in the Stony River overburden, the effect and relation of which coefficient to uplift pressure and resistance to sliding have been explained in Paragraph 2.

5.—The evidently unintentional misstatement is made that the writer "admits the presence of considerable hydrostatic pressures at a distance of 20 ft. from the down-stream side of the cut-off wall" (page 1031). The writer's actual statement, as given on page 998, is believed to be self-explanatory to a careful reader. The writer does not admit the presence of such considerable hydrostatic pressures; on the contrary, he desires again to point out that no pressure head of more than 2 ft. has been detected at the top of any weep-holes or drain pipes since the reconstruction was completed (pages 999-1000).

6.—The premises being erroneous, as shown above, Mr. Rutenberg arrives at a conclusion manifestly erroneous, namely, that "the up-stream half of the base is exposed to dangerous uplift pressures" (page 1031). This erroneous conclusion leads to a likewise erroneously applied train of "previously stated consequences" (for which see page 1031).

7.—Again, there is imputed to the writer cognizance of the actual existence of the rather strained hypothetical phenomena which Mr. Rutenberg sets up as to the possibility that "the drainage pipes will be filled through the higher perforations from the higher strata of the foundation soil, etc." (page 1032). It is conceded that such conditions might exist, but, if so, it is far from certain that the results would be harmful. Be that as it may, however, the phenomenon referred to by the writer (page 1000) clearly lends no weight whatsoever to the hypothetical conditions proposed.

Relative to this matter, it should be noted that the fact that so many of the weep-holes and drain pipes remain just full of water, but not over-flowing, is sufficient proof that the source of such water is ground-water, and that it is not the result of leakage from the reservoir. The writer is inclining more and more to a belief in the correctness of the explanation of the phenomenon on the basis of capillarity.

8.—From a casual inspection of Plate XII, Mr. Rutenberg ventures to pass judgment as to the strength of the anchoring wall at the heel. That the inspection must have been casual is shown by the fact that, contrary to his statement (page 1032), Plate XII does give the essential dimensions, and even the details, of the reinforcement of the anchoring wall at Bay 35. Furthermore, data as to the anchoring walls at Bays 30 and 31 are shown on Plate XIII.

Mr. Scheidenhelm.

An exposition of the detailed calculations involved in the design of the anchoring walls might have been included in the paper. However, even as it stands, the paper has been characterized as exhaustive. The addition of such an exposition, therefore, did not seem advisable, and at this date the military duties of the writer preclude such diversion on his part. Hence it must suffice to state that the anchoring walls at heel and toe were designed, with standard factors of safety, so as to carry, jointly and safely, all the horizontal thrust, excepting only an amount equal to the product of the weight of the superstructure (plus water load) multiplied, in the case of the clayey soil, by a coefficient of frictional resistance of 0.2 (page 978). The latter amount of horizontal thrust can certainly be counted on to be transferred into the foundation soil directly by the frictional resistance existing between the soil and the base of the superstructure. Essentially the same method has been used by Professor Cain, in the admirable analysis contained in his discussion (page 1050-51). The only difference is that Professor Cain there considers the writer's "frictional resistance" as subdivided into friction and "cohesion."

As a matter of fact, the results obtained by Professor Cain for the load carried directly from the base of the dam into the earth, and thence down to the "planes of least resistance", without being transferred through the anchoring walls at the heel or toe, are very much greater than those obtained by the writer by the use of the coefficient, 0.2. It will be noted that the coefficient assumed by the writer for this particular purpose is only 80% of the "probable minimum value" shown in Table 1; and, as such, it is believed to be thoroughly conservative, with the purpose and result that the anchoring walls were correspondingly built so much the stronger.

9.—The fear is expressed that the toe-wall "will aid in collecting the leakage under the dam" (page 1033). Inasmuch as weep-holes were left through the footings (see Plate XII), it is not believed that the hydrostatic pressure in the foundation soil at the toe-wall can be sufficient (the depth of the wall considered) to require relief through the toe-wall. An exception exists in the case of the old spillway, where the toe-wall is especially deep (17 ft.). There, drainage openings were provided through the vertical member of the toe-wall, the details of which are shown in Fig. 27.

10.—With reference to the effect of the heel-wall and its "under-cut slope" (page 1033), the attention of Mr. Rutenberg is respectfully called to the physical fact that the heel-wall cannot possibly present additional surface for the application of uplift pressure without at the same time presenting additional surface for the application of downward water pressure, which, of course, resists overturning. Even granting that the up-stream portion of the heel-wall is subjected to full hydrostatic pressure on the "under-cut slope", the net effect of

Mr. Scheidenhelm.

the heel-wall would still be to resist overturning, for the reason that the specific gravity of the heel-wall concrete is much greater than that of the water which it displaces. In this respect the location of the heel-wall so far up stream, and its correspondingly great lever arm, are of no small consequence in actually increasing the stability of the structure against overturning. Manifestly, the result is diametrically opposite to that stated in the discussion.

11.—The writer quite agrees with the implication regarding the tests of frictional resistance of various Stony River soils, to the extent that it would be dangerous to rely on these as giving truly representative results (page 1033). However, it by no means follows that the tests are "without practical value." On what is our knowledge of the frictional resistance of soils based, if not on observation and tests, as well as on theory? It should have been unnecessary again to point out what was evidently overlooked, namely, that the writer discounted the test results to such a degree that, instead of assuming an average coefficient of 0.61, he based the design on a coefficient of 0.33 (page 953). Moreover, the structure is shown actually to be safe with a coefficient of 0.25.

12.—Similarly, it should not have been necessary to remind any one that no pretense has been made by the writer that the weight of the underlying foundation soil aids, in the least, to resist overturning. The weight of the underlying foundation soil is utilized solely to resist failure by sliding. Of course, once such soil has been washed away, it can no longer resist sliding; but failure resulting from such conditions would have been due primarily to leakage or undermining; and against failure of that sort entirely different precautions have been taken.

13.—Mr. Rutenberg is under a misapprehension as to the writer's "adding 3½ ft. of water to the original level in the reservoir" (page 1034). As a matter of fact, the writer did not add to the water level, but merely made provision for taking care of floods, which would have come with equal probability in the cases of the original and the strengthened structure. True, a parapet was added to prevent overflow at the bulkhead sections and consequent undermining at the down-stream edges of those sections. However, that the additional horizontal water pressure caused thereby is negligible should be patent to every one with a moment's computation. On the other hand, the new spillway serves to hold down the water level in the reservoir for a given flood discharge, as compared with the water level which would have existed in the case of the original structure for the same flood discharge. It is pertinent to note that, for instance, even on the basis of a run-off of 1 386 sec-ft. per sq. mile (as reported for Cane Creek, page 926), the bulkhead section of the original structure would have been overtopped by 2½ ft. That is, such a discharge could have

Mr. Scheidenhelm.

taken place only after the water level had risen to an elevation of about 141.5. The corresponding water level under the new conditions for a spillway discharge of 1 386 sec-ft. per sq. mile will be approximately at Elevation 141.65. Evidently, the difference is negligible.

Again, reference to Table 3 will show that the same elevation of head-water, namely 140.5, was used for the stability analyses for both the original and the strengthened structures under "normal maximum load."

14.—It is true that the superstructure of the new spillway section is heavier than that of the original portions of the dam. However, it does not follow, by any means, that either "the original structure is insufficient or the excess of the new is useless" (page 1034). As to the original structure, the writer was forced to choose, on the one hand, between recommending the expenditure of a relatively enormous sum of money in order to strengthen the decks and buttresses, and, on the other hand, accepting somewhat higher working stresses than would have been allowed had the structure been designed initially for the water loading for which it should have been designed. As to the new spillway, the increased cost of using normal working stresses, as compared with the cost for the slightly higher stresses obtaining in the original portions of the dam, for the same loading, was not great, and there would have been no justification for holding down the new spillway dimensions to correspond with those of the original structure (page 1005). A situation of this sort requires the use of common sense as well as the application of theory.

15.—The unit bearing stresses for the soil and the base of the dam, the necessary data for the computation of which Mr. Rutenberg misses (page 1034), are set forth in considerable detail on pages 978-982. Further details might have been added had it been desirable to extend indefinitely the limits of the paper.

16.—The writer is unable to agree that the reservoir or ground-water leakage, mentioned on page 1000 and discussed on page 1035, has found other opportunities for "harmful erosion." Mere differences of opinion are immaterial, but it is to the point to know that since about a month after the reservoir had completely filled, there have been no further appearances of muddy water at any of the many drainage openings in the dam. This fact would seem to bear out the writer's opinion (page 1000) that the muddy nature of the water which appeared was due to adjustments in the foundation soil to the new conditions of loading.

The foregoing comments have been essentially on divergences from the facts. However, certain mere expressions of opinion on the part of Mr. Rutenberg seem to warrant passing mention. For instance, he "believes the reconstructed dam is less safe than the original structure" (page 1035) and "is firmly convinced that the reconstructed dam will

Mr. Scheidenhelm.

also be broken, perhaps soon, if adequate repairs are not made in time" (page 1035). It is unfortunate that opinions of so grave a nature and predictions so dire should be advanced, based, as they are, on erroneous premises, and certainly not substantiated by the facts. Probably the most important considerations in this regard are the results of the reconstruction, which speak for themselves:

a.—In the first place, the reconstructed dam has now stood for more than 2 years under full water load. The original structure stood only 65 days under full water load prior to failure.

b.—Shortly after the reconstruction was completed, the dam was subjected to a flood which caused the head-water to rise about 3½ ft. higher than the highest water level which had occurred during the short life of the original structure.

c.—Finally, an inspection made recently by the writer showed that the dam is in excellent condition.

Certain criticisms have been offered by Mr. Moore (page 1035), Two of these in effect duplicate criticisms made by Mr. Rutenberg, namely, as to the value of the writer's tests of frictional resistance and as to the structural strength of the new anchoring walls at the heel of the dam. The writer's comments in regard to these criticisms may be found in the paragraphs numbered 11 and 8, respectively.

The contingency of the fracture of the anchoring wall at the heel, to which Mr. Moore refers, is not believed by the writer to be a serious one. The extent to which such considerations are pertinent is a matter of judgment, as to which it is not surprising to find differences of opinion. Had it been considered necessary by the writer, the heel-wall and toe-wall could, and would, have been made even deeper, thus further reducing the unit soil pressures caused by such horizontal thrust as is transferred by the anchoring walls into the foundation soil. The writer desires, further, to point out that it would be impossible to have uplift pressures from both clay and water acting on the same areas of the base of the dam. Inasmuch, therefore, as certain allowances were made for the uplift pressure of water (Table 3), it is evident that considerable provision has already been made for flotation effect, if any, on part of the foundation soil.

The "floating off" of a dam is, in the writer's opinion, a fanciful expression rather than a serious possibility. He has yet to learn of an actual case of floating of a dam on either water or soil. Nevertheless, he does not mean to belittle the possibilities and effect of uplift pressure, as is shown by the load assumptions set forth in Table 3 under the "most severe conditions within limits of reason."

Again, Mr. Moore states that the water assumed to flow over the intermediate spillway would not fall "well-nigh" vertically. Although desirous of avoiding any hair-splitting discussion as to what "well-nigh" vertically means, the writer wishes to state that the upper and

Mr. Scheidenhelm.

lower nappes of the over-falling water were determined according to the results of the experimentation of M. Bazin, and the tumbling hearth mentioned (page 931) was designed accordingly. It is interesting to note that Mr. Brodie in his discussion (page 1043) mentions that his own checking gave results practically identical with those of the writer for the shape of the new spillway crest. The same method was used by the writer in determining the shape of the new spillway crest as in determining the nappes of the over-falling sheet of water at the intermediate spillway. The fact that both studies were based on the work of M. Bazin explains the close check between the results obtained by Mr. Brodie and by the writer.

The real value of the use of the brittle steel pins as flash-board supports is no longer a matter of doubt; the results of three seasons of operation speak for themselves. Thus far, the pins and flash-boards have allowed the undisturbed and safe utilization of the 25% additional capacity of the reservoir made available by the use of the flash-boards. The writer does not pretend that any and all brittle steel pins will accomplish such results, but does believe that merit is justly attributable to the pins adopted in the present case.

In addition to the foregoing, certain scattered comments appear to be appropriate to round out the closure of the discussion:

Mr. Finch very properly emphasizes the advisability of paying more attention to the architectural treatment of dams, etc. (page 1029). In this the writer entirely agrees, even though special treatment was not necessary or warranted in an isolated location like that of the dam under discussion. The type of treatment, of course, had been fixed before the writer's arrival on the scene. It is noteworthy, however, that the construction of a second spillway gave a balancing effect, especially to the down-stream view of the dam, which the original structure entirely lacked.

With reference to Mr. Downs' discussion of the coefficients of frictional resistance of Appalachian materials (page 1036), it is well to remember that though the tests showed an average coefficient of 0.61, the designs were actually based on a probable coefficient of 0.33, and that it is designed to be safe for a coefficient of 0.25, without reliance on the shearing resistance of the clayey soil.

On the several questions raised by Mr. Dunham (page 1039), the writer is unable to shed any light. Most of the questions do not fall within the scope of his investigation, and it is not believed to be appropriate to extend the present discussion by a consideration of the possibilities of imitating Nature's regulation of the flow of streams. The use of the increased flow of the river for power purposes was not contemplated.

Mr. Gregory expresses concern as to the advisability of placing tar-paper in the joints of a dam (page 1060). In the case of this dam,

Mr. Scheidenhelm.

this material was not expected to be permanent, and it is believed that, as the tar-paper gradually disappears, in years to come, it will simultaneously be replaced by sediment and accretions resulting from the action of the reservoir water on the concrete, particularly the alkaline elements thereof.

It was economy that dictated the use of such an expedient as tar-paper; yet its immediate effectiveness appears to have been as great as one could expect from any other method. The leakage through the joints has actually become negligible, and that, of course, is the result sought. A leakage proportionate to that reported by Mr. Gregory as having existed at the Ashokan Dam (page 1064) would have been intolerable at Stony River, in view of the relatively small reservoir capacity available in the latter case. It is interesting to note that the initial daily leakage at the Ashokan Dam was approximately one-quarter of the total storage capacity of the Stony River Reservoir. Possibly the reduction in leakage in the former case has likewise been due to sedimentation; such an effect has frequently been observed by the writer.

The percentage of "plums" specified in connection with the Class *C* concrete was intended to fix a maximum limit, and does not represent an average of the quantity actually used. As a matter of fact, a maximum limit need hardly be fixed. At any rate, the writer agrees with Mr. Jorgensen that 20% of "plums" represents a very high average (page 1071). The writer does not know the actual quantity of "plums" placed in the Class *C* concrete at Stony River.

The mathematical solution presented (page 1076) by Professor Church, for determining portions of curves showing "discharge over spillways", such as used in Figs. 12 to 15, is indeed most interesting, utilizing, as it does, methods of attack in which Professor Church is a past master.

Unfortunately, quantitive measurements of leakage were not made on May 25th and November 1st, 1915, as referred to by Mr. O'Shaughnessy.

Mr. Justin offers an alternative suggestion for combining means to increase resistance to sliding and to increase the length of the path which leakage water from the reservoir must follow. The essentials of these means are shown in Fig. 39. With reference to the first phase of the suggestion, it may be said that preliminary studies along the same line, namely, of increasing the weight of superstructure (page 959), showed that nothing short of a complete filling of the available space with masonry or concrete would suffice. Of course, the considerations regarding overloading of the foundation soil at the toe were applied to the base as actually, and materially, widened by the building of the new toe-wall. Had the expedient of increasing the superstructure weight been adopted, it would naturally have been

Mr. Scheidenhelm.

advisable, as Mr. Justin suggests, to place the added weight as far up stream as possible. Unfortunately, however, the slope of the deck would have precluded obtaining any material advantage thereby.

A similar method of transferring the load from the buttress into the toe-wall was actually used in the reconstruction in connection with the special work at the outlet gate bays (see Plate XIII).

As to the lengthening of the path of travel of leakage water, the writer believes that reliance may be placed on this method more safely in the case of gravel or sand foundations than where loam and clay are involved, as at the Stony River site. It should also be noted that the corresponding widening of the base of the dam, assuming an entire absence of drainage openings through the base, would increase the allowance necessary to be made for uplift pressure.

In the case of the suggested up-stream concrete apron, absolute water-tightness would be imperative, and therein, the writer believes, would lie the greatest difficulty, especially if the apron were made only 6 in. thick. Furthermore, the original cut-off wall is much less pervious than the soil which would underlie the suggested apron. Consequently, the result would probably be a gradual accumulation of water under pressure under the apron, with resulting decrease in the efficacy of the expedient. This would be true even if the reservoir water could penetrate under the apron only at its up-stream edge.

Although it was considered well worth while to make the expensive addition of anchoring walls to the original structure, it should be remembered that the same results could have been obtained much more easily and economically had a combination of anchoring wall at the heel and of cut-off been constructed as a part of the dam at the very beginning. For a case of original construction, therefore, the advantages of using the principle of anchoring walls are even more apparent.

The West Virginia Pulp and Paper Company is following the praiseworthy course of having annual inspections of the dam made by an experienced engineer; moreover, there is the additional safeguard of daily inspections by a regular attendant.

In conclusion, the writer wishes to express his satisfaction with the magnanimous approval contained in the discussions by Mr. Coburn, Chief Engineer of the Ambursen Company, and by Mr. Wegmann, who had been retained in an advisory capacity during the period when the original construction of the dam was under consideration.

Paper No. 1398

FINAL REPORT OF THE SPECIAL COMMITTEE ON CONCRETE AND REINFORCED CONCRETE*

WITH DISCUSSION BY MESSRS. A. H. RHETT, WILLIAM FRY SCOTT, CARL GAYLER, H. V. HINCKLEY, HENRY T. EDDY, C. A. P. TURNER, F. E. TURNEAURE, AND A. N. TALBOT.†

TO THE PRESIDENT AND MEMBERS OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS:

GENTLEMEN.—Your Special Committee on Concrete and Reinforced Concrete herewith presents, as its Final Report, the result of the joint efforts of its own members and of the representatives of other Societies appointed for the same purpose.

Respectfully submitted,

JOSEPH R. WORCESTER,
Chairman,
RICHARD L. HUMPHREY,
Secretary,
J. E. GREINER,
W. K. HATT,
OLAF HOFF,
ROBERT W. LESLEY,
EMIL SWENSSON,
ARTHUR N. TALBOT.

NOVEMBER 17TH, 1916.

* Presented to the Annual Meeting, January 17th, 1917.

† Discussions on this report, by Messrs. L. J. Mensch, G. S. Bergendahl, and E. S. Martin were printed in the October, 1917, *Proceedings*, but are not published here because the Committee has not had sufficient time to consider and reply to them. These discussions, together with any reply the Committee may make, if so ordered by the Publication Committee, may be published later. It seems desirable, however, to publish the report in this volume, otherwise its publication would be delayed for a year.

FINAL REPORT

OF THE

JOINT COMMITTEE ON CONCRETE

AND REINFORCED CONCRETE

PRELIMINARY DRAFT PREPARED AND SUBMITTED BY THE SECRETARY, OCTOBER 27TH, 1908.

AMENDED AND ADOPTED BY LETTER-BALLOT OF THE COMMITTEE, DECEMBER 20TH, 1908.

REVISED AND BROUGHT UP TO DATE, NOVEMBER 20TH, 1912.

FINAL REPORT ADOPTED BY THE COMMITTEE, JULY 1ST, 1916.

AFFILIATED COMMITTEES

Discussion 1153

CHAPTER I.

Introduction.

The Joint Committee on Concrete and Reinforced Concrete was formed by the union of Special Committees appointed in 1903 and 1904 by the American Society of Civil Engineers, the American Society for Testing Materials, the American Railway Engineering and Maintenance of Way Association (now the American Railway Engineering Association), and the Association of American Portland Cement Manufacturers (now the Portland Cement Association). In 1915 there was added a Special Committee appointed by the American Concrete Institute at the invitation of the Joint Committee.

The present organization and membership of the Joint Committee is as follows:

Officers.

Chairman—Joseph R. Worcester.
Vice-Chairman—Emil Swensson.
Secretary—Richard L. Humphrey.

Members.

American Society of Civil Engineers.

John E. Greiner, Consulting Engineer, Baltimore, Md.
William K. Hatt, Professor of Civil Engineering, Purdue University, Lafayette, Ind.
Olaf Hoff, Consulting Engineer, 149 Broadway, New York, N. Y.
Richard L. Humphrey, Consulting Engineer, 805 Harrison Building, Philadelphia, Pa.
Robert W. Lesley, Past-President, Association of American Portland Cement Manufacturers, Pennsylvania Building, Philadelphia, Pa.
Emil Swensson, Consulting Engineer, 925 Frick Building, Pittsburgh, Pa.
Arthur N. Talbot, Professor of Municipal and Sanitary Engineering, University of Illinois, Urbana, Ill.
Joseph R. Worcester, Consulting Engineer, 79 Milk Street, Boston, Mass.

American Society for Testing Materials.

William B. Fuller, Consulting Engineer, 150 Nassau Street, New York, N. Y.
Edward E. Hughes, General Manager, Franklin Steel Works, Franklin, Pa.
Richard L. Humphrey, Consulting Engineer, 805 Harrison Building, Philadelphia, Pa.

ALBERT L. JOHNSON, First Vice-President and General Manager, Corrugated Bar Company, Mutual Life Building, Buffalo, N. Y.

ROBERT W. LESLEY, Past-President, Association of American Portland Cement Manufacturers, Pennsylvania Building, Philadelphia, Pa.

GAETANO LANZA, The Montevista, Sixty-third and Oxford Streets, Overbrook, Philadelphia, Pa.

LEON S. MOISSEIFF, Consulting Engineer, 69 Wall Street, New York, N. Y.

HENRY H. QUIMBY, Chief Engineer, Department of City Transit, Bourse Building, Philadelphia, Pa.

SANFORD E. THOMPSON, Consulting Engineer, 136 Federal Street, Boston, Mass.

FREDERICK E. TURNEAURE, Dean of College of Mechanics and Engineering, University of Wisconsin, Madison, Wis.

SAMUEL TOBIAS WAGNER, Chief Engineer, Philadelphia and Reading Railway Company, Reading Terminal, Philadelphia, Pa.

GEORGE S. WEBSTER, Director, Wharves, Docks, and Ferries, Bourse Building, Philadelphia, Pa.

AMERICAN RAILWAY ENGINEERING ASSOCIATION.

H. A. CASSIL, Division Engineer, Baltimore and Ohio Railway Company, New Castle, Pa.

FREDERICK E. SCHALL, Bridge Engineer, Lehigh Valley Railway Company, South Bethlehem, Pa.

FREDERICK P. SISSON, Assistant Engineer, Grand Trunk Railway, Detroit, Mich.

JOSEPH J. YATES, Bridge Engineer, Central Railroad of New Jersey, 143 Liberty Street, New York, N. Y.

PORTLAND CEMENT ASSOCIATION.

NORMAN D. FRASER, President, Chicago Portland Cement Company, 30 North La Salle Street, Chicago, Ill.

ROBERT E. GRIFFITH, Vice-President, Giant Portland Cement Company, Pennsylvania Building, Philadelphia, Pa.

SPENCER B. NEWBERRY, President, Sandusky Portland Cement Company, Engineers' Building, Cleveland, Ohio.

AMERICAN CONCRETE INSTITUTE.

EDWARD GODFREY, Structural Engineer, Robert W. Hunt & Co., Monongahela Building, Pittsburgh, Pa.

EGBERT J. MOORE, Chief Engineer, Turner Construction Company, 11 Broadway, New York, N. Y.

LEONARD C. WASON, President, Aberthaw Construction Company, 27 School Street, Boston, Mass.

Progress reports by the Joint Committee were presented to the parent societies in 1909 and 1912. The report presented in 1912 has been printed by the American Society of Civil Engineers, the American Society for Testing Materials, and the American Railway Engineering Association, and reference to that report may be made for details regarding the earlier work of the Joint Committee, a historical sketch of the introduction of concrete and reinforced concrete, and a bibliography of authorities upon which the report was based.

The Committee has been much gratified at the reception accorded its 1912 report, and realizes the responsibility which rests upon it because of the very extensive adoption of its recommendations in current practice in this country. The members of the Committee are well aware of the incompleteness of that report, and even now they are unable to pass judgment upon some matters not dealt with in the present report.

Since 1912 the Committee has continued its study of the subject, has followed the working out of its recommendations in actual construction, has weighed arguments and criticisms which have come to its attention, and has considered new experimental data. While the Committee sees no reason for making any fundamental changes, the recommendations of its previous report have been revised to some extent, and considerable new material has been added upon subjects not previously touched. There are some subjects upon which experimentation is still in progress, and the art of concrete and reinforced concrete will be advancing for many years to come.

While this report deals with every kind of stress to which concrete is subjected, and includes all ordinary conditions of proportioning and handling, it does not go into all types of construction nor all the applications to which concrete and reinforced concrete may be put. The report is not a specification, but may be used as a basis for specifications. In their use, concrete and reinforced concrete involve the exercise of good judgment to a greater degree than do any other building materials. Rules cannot produce or supersede judgment; on the contrary, judgment should control the interpretation and application of rules.

The Committee has not attempted in every case to present rigidly scientific methods of analysis in dealing with stresses, but has aimed to furnish rules which will lead to safe results sufficiently close for ordinary design.

The Committee presumes that the application of the recommendations in this report to the design of any structure will be made only by persons having an adequate knowledge of the principles of structural design. Only persons with such knowledge and experience should be called upon to design reinforced concrete structures.

The Joint Committee has reached the conclusion that, with this effort to express the present state of the art, it would be desirable for it to withdraw from the field. This action has been taken in the hope that a work similar to that which the Committee has attempted to perform will again be undertaken, within a reasonable term of years, in order that there may be some authoritative body to consider and pass upon newly acquired knowledge and information gleaned from experience. The Committee feels certain, however, that it would be for the better interest of the profession to entrust this work to other hands rather than to continue the present organization with this object in view.

CHAPTER II.

Adaptability of Concrete and Reinforced Concrete.

The adaptability of concrete and reinforced concrete for engineering structures or parts thereof, is so well established that they are recognized materials of construction. When properly used, they have proved satisfactory for those purposes for which their qualities make them particularly suitable.

1. USES.

Plain concrete is well adapted for structures in which the principal stresses are compressive, such as: foundations, dams, retaining and other walls, tunnels, piers, abutments, and, in many cases, arches.

By the use of metal reinforcement to resist the principal tensile stresses, concrete becomes available for general use in various structures and structural forms. This combination of concrete and metal is particularly advantageous in structural members subject to both compression and tension, and in columns where, although the main stresses are compressive, there is also cross-bending.

Metal reinforcement may also be used to advantage to distribute and minimize cracks due to shrinkage and temperature changes.

2. PRECAUTIONS.

Failures of reinforced concrete structures have been due usually to some one or more of the following causes:

Defective design, poor material, faulty execution, or premature removal of forms.

To prevent failures or otherwise unsatisfactory results, the following precautions should be taken:

The computations and assumptions on which the design is based should be in accordance with the established principles of mechanics. The unit stresses and details of the design should conform to ac-

cepted good practice. Materials used for the concrete as well as for the reinforcement should be carefully inspected and tested, special attention being given to the testing of the sand, as poor sand has proved a frequent cause of failure. The measuring and combining of the materials which go to make up the concrete, and the placing of the concrete in the forms, should be under the supervision of experienced men. The metal for reinforcement should be of a quality conforming to standard specifications. Care should be taken to obtain good bond between different fills of concrete, to prevent concrete from freezing before the cement has set, to have the materials thoroughly mixed, to avoid too wet or too dry a consistency, and to have the forms cleaned before concrete is placed.

The computations should include all details; even minor details may be of the utmost importance. The design should show clearly the size and position of the reinforcement, and should provide for proper connection between the component parts so that they cannot be displaced. As the connections between reinforced concrete members are frequently a source of weakness, the design should include a detailed study of such connections.

The concrete should be rigidly supported until it has developed sufficient strength to carry imposed loads. The most careful and experienced inspection is necessary to determine when the concrete has set sufficiently for it to be safe to remove forms. Frozen concrete frequently has been mistaken for properly set concrete.

3. DESIGN AND SUPERVISION.

The execution of the work should not be separated from the design, as intelligent supervision and successful execution can be expected only when both functions are combined. It is desirable, therefore, that the engineer who prepares the design and specifications should have supervision of the execution of the work.

The Committee recommends the following practice for the purpose of fixing the responsibility and providing for adequate supervision during construction.

(*a*) Before work is commenced, complete plans and specifications should be prepared, giving the dead and live loads, wind and impact, if any, and working stresses, showing the general arrangement and all details. The plans should show the size, length, location of points of bending, and exact position of all reinforcement, including stirrups, ties, hooping, and splicing.

(*b*) The specifications should state the qualities of the materials and the proportions in which they are to be used.

(*c*) The strength which the concrete is expected to attain after a definite period should be stated in the specifications.

(*d*) Inspection during construction should be made by competent inspectors selected by and under the supervision of the engineer, and should cover the following:

1. Materials.
2. Construction and erection of the forms and supports.
3. Sizes, shapes, arrangement, position, and fastening of the reinforcement.
4. Proportioning, mixing, consistency, and placing of the concrete.
5. Strength of the concrete by tests of standard test pieces made on the work.
6. Whether the concrete is sufficiently hardened before the forms and supports are removed.
7. Protection from injury of all parts of the structure.
8. Comparison of dimensions of all parts of the finished structure with the plans.

(*e*) Load tests on portions of the finished structure should be made where there is reasonable suspicion that the work has not been properly performed, or that, through influences of some kind, the strength has been impaired, or where there is any doubt as to the sufficiency of the design. The loading should be carried to such a point that the calculated stresses under such loading shall be one and three-quarters times the allowed working stresses, and such loads should cause no injurious permanent deformations. Load tests should not be made before the concrete has been in place 60 days.

4. DESTRUCTIVE AGENCIES.

(*a*) *Corrosion of Metal Reinforcement.*—Tests and experience indicate that steel sufficiently embedded in good concrete is well protected against corrosion, no matter whether located above or below water level. It is recommended that such protection be not less than 1 in. in thickness. If the concrete is porous so as to be readily permeable by water, as when the concrete is laid with a very dry consistency, the metal may corrode on account of the presence of moisture and air.

(*b*) *Electrolysis.*—The experimental data available on this subject seem to show that while reinforced concrete structures may, under certain conditions, be injured by the flow of electric current in either direction between the reinforcing material and the concrete, such injury is generally to be expected only where voltages are considerably higher than those which usually occur in concrete structures in practice. If the iron be positive, trouble may manifest itself by corrosion of the iron accompanied by cracking of the concrete, and, if the iron be negative, there may be a softening of the concrete near the surface of the iron, resulting in a destruction of the bond. The former, or anode effect, decreases much more rapidly than the voltage, and almost

if not quite disappears at voltages that are most likely to be encountered in practice. The cathode effect, on the other hand, takes place even for very low voltages, and is therefore more important from a practical standpoint than that of the anode.

Structures containing salt or calcium chloride, even in very small quantities, are very much more susceptible to the effects of electric currents than normal concrete, the anode effect progressing much more rapidly in the presence of chlorine, and the cathode effect being greatly increased by the presence of an alkali metal.

There is great weight of evidence to show that normal reinforced concrete structures free from salt are in very little danger under most practical conditions, while non-reinforced concrete structures are practically immune from electrolysis troubles.

(*c*) *Sea Water.*—The data available concerning the effect of sea water on concrete or reinforced concrete are limited and inconclusive. Sea walls out of the range of frost action have been standing for many years without apparent injury. In many places serious disintegration has taken place. This has occurred chiefly between low and high tide levels, and is due, evidently, in part to frost. Chemical action also appears to be indicated by the softening of the mortar. To effect the best resistance to sea water, the concrete must be proportioned, mixed, and placed so as to prevent the penetration of sea water into the mass or through the joints. The aggregates should be carefully selected, graded, and proportioned with the cement so as to secure the maximum possible density; the concrete should be thoroughly mixed; the joints between old and new work should be made water-tight; and the concrete should be kept from exposure to sea water until it is thoroughly hard and impervious.

(*d*) *Acids.*—Dense concrete thoroughly hardened is affected appreciably only by acids which seriously injure other materials. Substances like manure, that contain acids, may injuriously affect green concrete, but do not affect concrete that is thoroughly hardened.

(*e*) *Oils.*—Concrete is unaffected by such mineral oils as petroleum and ordinary engine oils. Oils which contain fatty acids produce injurious effects, forming compounds with the lime which may result in a disintegration of the concrete in contact with them.

(*f*) *Alkalies.*—The action of alkalies on concrete is problematical. In the reclamation of arid land, where the soil is heavily charged with alkaline salts, it has been found that concrete, stone, brick, iron, and other materials are injured under certain conditions. It would seem that at the level of the ground-water in an extremely dry atmosphere such structures are disintegrated, through the rapid crystallization of the alkaline salts, resulting from the alternate wetting and drying of the surface. Such destructive action can be prevented by the use of a protective coating, and is minimized by securing a dense concrete.

CHAPTER III.

MATERIALS.

The quality of all the materials is of paramount importance. The cement and also the aggregates should be subject to definite requirements and tests.

1. CEMENT.

There are available for construction purposes Portland, Natural, and Puzzolan or Slag cements.

(*a*) *Portland Cement* is the product obtained by finely pulverizing clinker produced by calcining to incipient fusion, an intimate and properly proportioned mixture of argillaceous and calcareous materials, with no additions subsequent to calcination excepting water and calcined or uncalcined gypsum.

It has a definite chemical composition varying within comparatively narrow limits.

Portland cement only should be used in reinforced concrete construction or in any construction that will be subject to shocks, vibrations, or stresses other than direct compression.

(*b*) *Natural Cement* is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature only sufficient to drive off the carbonic acid gas.

Although the limestone must have a certain composition, this composition may vary within much wider limits than in the case of Portland cement. Natural cement does not develop its strength as quickly nor is it as uniform in composition as Portland cement.

Natural cement may be used in massive masonry where weight rather than strength is the essential feature.

Where economy is the governing factor, a comparison may be made between the use of natural cement and a leaner mixture of Portland cement that will develop the same strength.

(*c*) *Puzzolan or Slag Cement* is the product resulting from finely pulverizing a mechanical mixture of granulated basic blast-furnace slag and hydrated lime.

Puzzolan cement is not nearly as strong, uniform, or reliable as Portland or natural cement, is not used extensively, and never in important work; it should be used only for unimportant foundation work underground where it is not exposed to air or running water.

(*d*) *Specifications.*—The cement should meet the requirements of the specifications and methods of tests for Portland cement, which are the result of the joint labors of Special Committees of the American Society of Civil Engineers, American Society for Testing Materials, American Railway Engineering Association, and other affiliated organizations, and the United States Government.

2. AGGREGATES.

Extreme care should be exercised in selecting the aggregates for mortar and concrete, and careful tests made of the materials for the purpose of determining the quality and grading necessary to secure maximum density[1] or a minimum percentage of voids. Bank gravel should be separated by screening into fine and coarse aggregates and then used in the proportions to be determined by density tests.

(*a*) *Fine Aggregate* should consist of sand, or the screenings of gravel or crushed stone, graded from fine to coarse, and passing when dry a screen having ¼-in. diameter holes;[2] it preferably should be of siliceous material, and not more than 30% by weight, should pass a sieve having 50 meshes per lin. in.; it should be clean, and free from soft particles, lumps of clay, vegetable loam or other organic matter.

Fine aggregate should always be tested for strength. It should be of such quality that mortar composed of one part Portland cement and three parts fine aggregate by weight when made into briquettes, prisms or cylinders will show a tensile or compressive strength, at an age of not less than 7 days, at least equal to the strength of 1:3 mortar of the same consistency made with the same cement and standard Ottawa sand.[3] If the aggregate be of poorer quality, the proportion of cement should be increased to secure the desired strength. If the strength developed by the aggregate in the 1:3 mortar is less than 70% of the strength of the Ottawa-sand mortar, the material should be rejected. In testing aggregates care should be exercised to avoid the removal of any coating on the grains, which may affect the strength; bank sands should not be dried before being made into mortar, but should contain natural moisture. The percentage of moisture may be determined upon a separate sample for correcting weight. From 10 to 40% more water may be required in mixing bank or artificial sands than for standard Ottawa sand to produce the same consistency.

(*b*) *Coarse Aggregate* should consist of gravel or crushed stone which is retained on a screen having ¼-in. diameter holes, and should be graded from the smallest to the largest particles; it should be clean, hard, durable, and free from all deleterious matter. Aggregates containing dust and soft, flat, or elongated particles, should be excluded. The Committee does not feel warranted in recommending the use of blast-furnace slag as an aggregate, in the absence of adequate data as to its value, especially in reinforced concrete construction. No

[1] A convenient coefficient of density is the ratio of the sum of the volumes of solid particles contained in a unit volume to the total unit volume.

[2] If the dividing size between the fine and coarse aggregate is less or greater than ¼ in., allowance should be made in grading and proportioning.

[3] A natural sand obtained at Ottawa, Illinois, passing a screen having 20 meshes and retained on a screen having 30 meshes per linear inch; prepared and furnished by the Ottawa Silica Company, for 2 cents per pound f. o. b. cars, Ottawa, Illinois.

satisfactory specifications or methods of inspection have been developed that will control its uniformity and ensure the durability of the concrete in which it is used.

The aggregate must be small enough to produce with the mortar a homogeneous concrete of sluggish consistency which will pass readily between and easily surround the reinforcement and fill all parts of the forms. The maximum size of particles is variously determined for different types of construction from that which will pass a ¼-in. ring to that which will pass a 1½-in. ring.

For concrete in large masses the size of the coarse aggregate may be increased, as a large aggregate produces a stronger concrete than a fine one; however, it should be noted that the danger of separation from the mortar becomes greater as the size of the coarse aggregate increases.

Cinder concrete should not be used for reinforced concrete structures, except in floor-slabs not exceeding 8-ft. span. It also may be used for fire protection purposes where not required to carry loads. The cinders used should be composed of hard, clean, vitreous clinker, free from sulphides, unburned coal, or ashes.

3. WATER.

The water used in mixing concrete should be free from oil, acid, alkali, or organic matter.

4. METAL REINFORCEMENT.

The Committee recommends as a suitable material for reinforcement, steel of structural grade filling the requirements of the Specifications for Billet Steel Concrete Reinforcement Bars of the American Society for Testing Materials.

For reinforcing slabs, small beams, or minor details, or for reinforcing for shrinkage and temperature stresses, steel wire, expanded metal, or other reticulated steel may be used, with the unit stresses hereinafter recommended.

The reinforcement should be free from flaking, rust, scale, or coatings of any character which would tend to reduce or destroy the bond.

CHAPTER IV.

MIXING AND PLACING.

1. PROPORTIONS.

The materials should be carefully selected, of uniform quality, and proportioned with a view to securing as nearly as possible a maximum density, which is obtained by grading the aggregates so that the smaller particles fill the spaces between the larger, thus reducing the voids in the aggregate to the minimum.

(*a*) *Unit of Measure.*—The measurement of the fine and coarse aggregates should be by loose volume. The unit of measure should be a bag of cement, containing 94 lb. net, which should be considered the equivalent of 1 cu. ft.

(*b*) *Relation of Fine and Coarse Aggregates.*—The fine and coarse aggregates should be used in such proportions as will secure maximum density. These proportions should be carefully determined by density experiments, and the grading of the fine and coarse aggregates should be uniformly maintained, or the proportions changed, to meet the varying sizes.

(*c*) *Relation of Cement and Aggregates.*—For reinforced concrete construction, one part of cement to a total of six parts of fine and coarse aggregates measured separately should generally be used. For columns, richer mixtures are preferable. In massive masonry or rubble concrete, a mixture of 1:9 or even 1:12 may be used.

These proportions should be determined by the strength or other qualities required in the construction at the critical period of use. Experience and judgment based on observation and tests of similar conditions in similar localities are excellent guides as to the proper proportions for any particular case.

In important construction, advance tests should be made on concrete composed of the materials to be used in the work. These tests should be made by standardized methods, to obtain uniformity in mixing, proportioning, and storage, and in case the results do not conform to the requirements of the work, aggregates of a better quality or more cement should be used to obtain the desired quality of concrete.

2. MIXING.

The mixing of concrete should be thorough, and continue until the mass is uniform in color and homogeneous. As the maximum density and greatest strength of a given mixture depend largely on thorough and complete mixing, it is essential that this part of the work should receive special attention and care.

Inasmuch as it is difficult to determine, by visual inspection, whether the concrete is uniformly mixed, especially where aggregates having the color of cement are used, it is essential that the mixing should occupy a definite period of time. The minimum time will depend on whether the mixing is done by machine or hand.

(*a*) *Measuring Ingredients.*—Methods of measurement of the various ingredients should be used which will secure at all times separate and uniform measurements of cement, fine aggregate, coarse aggregate, and water.

(*b*) *Machine Mixing.*—The mixing should be done in a batch machine mixer of a type which will ensure the uniform distribution of

the materials throughout the mass, and should continue for the minimum time of 1½ min. after all the ingredients are assembled in the mixer. For mixers of two or more cubic yards capacity, the minimum time of mixing should be 2 min. Since the strength of the concrete is dependent upon thorough mixing, a longer time than this minimum is preferable. It is desirable to have the mixer equipped with an attachment for automatically locking the discharging device so as to prevent the emptying of the mixer until all the materials have been mixed together for the minimum time required after they are assembled in the mixer. Means should be provided to prevent aggregates being added after the mixing has commenced. The mixer should also be equipped with water storage, and an automatic measuring device which can be locked is desirable. It is also desirable to equip the mixer with a device recording the revolutions of the drum. The number of revolutions should be so regulated as to give at the periphery of the drum a uniform speed; about 200 ft. per min. seems to be the best speed in the present state of the art.

(*c*) *Hand Mixing.*—Hand mixing should be done on a water-tight platform and especial precautions taken after the water has been added, to turn all the ingredients together at least six times, and until the mass is homogeneous in appearance and color.

(*d*) *Consistency.*—The materials should be mixed wet enough to produce a concrete of such a consistency as will flow sluggishly into the forms and about the metal reinforcement when used, and which, at the same time, can be conveyed from the mixer to the forms without separation of the coarse aggregate from the mortar. The quantity of water is of the greatest importance in securing concrete of maximum strength and density; too much water is as objectionable as too little.

(*e*) *Retempering.*—The remixing of mortar or concrete that has partly set should not be permitted.

3. PLACING CONCRETE.

(*a*) *Methods.*—Concrete after the completion of the mixing should be conveyed rapidly to the place of final deposit; under no circumstances should concrete be used that has partly set.

Concrete should be deposited in such a manner as will permit the most thorough compacting, such as can be obtained by working with a straight shovel or slicing tool kept moving up and down until all the ingredients are in their proper place. Special care should be exercised to prevent the formation of laitance; where laitance has formed it should be removed, since it lacks strength, and prevents a proper bond in the concrete.

Before depositing concrete, the reinforcement should be carefully placed in accordance with the plans. It is essential that adequate

means be provided to hold it in its proper position until the concrete has been deposited and compacted; care should be taken that the forms are substantial and thoroughly wetted (except in freezing weather) or oiled, and that the space to be occupied by the concrete is free from débris. When the placing of concrete is suspended, all necessary grooves for joining future work should be made before the concrete has set.

When work is resumed, concrete previously placed should be roughened, cleansed of foreign material and laitance, thoroughly wetted and then slushed with a mortar consisting of one part Portland cement and not more than two parts fine aggregate.

The surfaces of concrete exposed to premature drying should be kept covered and wet for a period of at least 7 days.

Where concrete is conveyed by spouting, the plant should be of such a size and design as to ensure a practically continuous stream in the spout. The angle of the spout with the horizontal should be such as to allow the concrete to flow without a separation of the ingredients; in general an angle of about 27° or one vertical to two horizontal is good practice. The spout should be thoroughly flushed with water before and after each run. The delivery from the spout should be as close as possible to the point of deposit. Where the discharge must be intermittent, a hopper should be provided at the bottom. Spouting through a vertical pipe is satisfactory when the flow is continuous; when it is unchecked and discontinuous it is highly objectionable, unless the flow is checked by baffle plates.

(*b*) *Freezing Weather.*—Concrete should not be mixed or deposited at a freezing temperature, unless special precautions are taken to prevent the use of materials covered with ice crystals or containing frost, and to prevent the concrete from freezing before it has set and sufficiently hardened.

As the coarse aggregate forms the greater portion of the concrete, it is particularly important that this material be warmed to well above the freezing point.

The enclosing of a structure and the warming of the space inside the enclosure is recommended, but the use of salt to lower the freezing point is not recommended.

(*c*) *Rubble Concrete.*—Where the concrete is to be deposited in massive work, its value may be improved and its cost materially reduced by the use of clean stones, saturated with water, thoroughly embedded in and entirely surrounded by concrete.

(*d*) *Under Water.*—In placing concrete under water, it is essential to maintain still water at the place of deposit. With careful inspection, the use of tremies, properly designed and operated, is a satisfactory method of placing concrete through water. The concrete should be mixed very wet (more so than is ordinarily permissible) so that it

will flow readily through the tremie and into place with practically a level surface.

The coarse aggregate should be smaller than ordinarily used, and never more than 1 in. in diameter. The use of gravel facilitates mixing and assists the flow. The mouth of the tremie should be buried in the concrete so that it is at all times entirely sealed and the surrounding water prevented from forcing itself into the tremie; the concrete will then discharge without coming in contact with the water. The tremie should be suspended so that it can be lowered quickly when it is necessary either to choke off or prevent too rapid flow; the lateral flow preferably should be not over 15 ft.

The flow should be continuous in order to produce a monolithic mass and to prevent the formation of laitance in the interior.

In case the flow is interrupted, it is important that all laitance be removed before proceeding with the work.

In large structures it may be necessary to divide the mass of concrete into several small compartments or units, to permit the continuous filling of each one. With proper care it is possible in this manner to obtain as good results under water as in the air.

A less desirable method is the use of the drop-bottom bucket. Where this method is used, the bottom of the bucket should be released when in contact with the surface of the place of deposit.

CHAPTER V.

Forms.

Forms should be substantial and unyielding, in order that the concrete may conform to the design, and be sufficiently tight to prevent the leakage of mortar.

It is vitally important to allow sufficient time for the proper hardening of the concrete, which should be determined by careful inspection before the forms are removed.

Many conditions affect the hardening of concrete, and the proper time for the removal of the forms should be determined by some competent and responsible person.

It may be stated in a general way that forms should remain in place longer for reinforced concrete than is required for plain or massive concrete, and longer for horizontal than is required for vertical members.

In general it may be considered that concrete has hardened sufficiently when it has a distinctive ring under the blow of a hammer, but this test is not reliable, if there is a possibility that the concrete is frozen.

CHAPTER VI.

Details of Construction.

1. Joints.

(*a*) *In Concrete.*—It is desirable to cast an entire structure at one operation, but as this is not always possible, especially in large structures, it is necessary to stop the work at some convenient point. This should be selected so that the resulting joint may have the least possible effect on the strength of the structure. It is therefore recommended that the joint in columns be made flush with the lower side of the girders, or in flat slab construction at the bottom of the flare of the column head; that the joints in girders be at a point midway between supports, unless a beam intersects a girder at this point, in which case the joint should be offset a distance equal to twice the width of the beam; and that the joints in the members of a floor system should in general be made at or near the center of the span.

Joints in columns should be perpendicular to the axis, and in girders, beams, and floor-slabs, perpendicular to the plane of their surfaces. When it is necessary to provide for shear at right angles to the axis, it is permissible to incline the plane of the joint as much as 30° from the perpendicular. Joints in arch rings should be on planes as nearly radial as practicable.

Before placing the concrete on top of a freshly poured column a period of at least 2 hours should be allowed for the settlement and shrinkage.

Shrinkage and contraction joints may be necessary to concentrate cracks due to temperature in smooth even lines. The number of these joints which should be determined and provided for in the design will depend on the range of temperature to which the concrete will be subjected, and on the amount and position of the reinforcement. In massive work, such as retaining walls, abutments, etc., built without reinforcement, contraction joints should be provided, at intervals of from 25 to 50 ft. and with reinforcement from 50 to 80 ft.; the smaller the height and thickness, the closer the spacing. The joints should be tongued and grooved to maintain the alignment in case of unequal settlement. A groove may be formed in the surface as a finish to vertical joints.

Shrinkage and contraction joints should be lubricated by an application of petroleum oil or a similar material, to permit a free movement when the concrete expands or contracts.

The movement of the joint due to expansion and contraction may be facilitated by the insertion of a sheet of copper, zinc, or even tarred paper.

(*b*) *In Reinforcement.*—Wherever it is necessary to splice tension reinforcement the length of lap should be determined on the basis of

the safe bond stress, the stress in the bar and the shearing resistance of the concrete at the point of splice; or a connection should be made between the bars of sufficient strength to carry the stress. Splices at points of maximum stress in tension should be avoided. In columns, bars more than ¾ in. in diameter not subject to tension should have their ends properly squared and butted together in suitable sleeves; smaller bars may be lapped, as indicated for tension reinforcement. At foundations bearing plates should be provided for supporting the bars, or the bars may be carried into the footing a sufficient distance to transmit the stress in the steel to the concrete by means of the bearing and the bond resistance. In no case should reliance be placed upon the end bearing of bars on concrete.

2. SHRINKAGE AND TEMPERATURE CHANGES.

The stresses resulting from shrinkage due to hardening and contraction from temperature changes are important in monolithic construction, and unless cared for in the design will produce objectionable cracks; cracks cannot be entirely prevented, but the effects can be minimized.

Large cracks, produced by quick hardening or wide ranges of temperature, can be broken up to some extent into small cracks by placing reinforcement in the concrete; in long, continuous lengths of concrete, it is better to provide shrinkage joints at points in the structure where they will do little or no harm. Reinforcement is of assistance, and permits longer distances between shrinkage joints than when no reinforcement is used.

Provision for shrinkage should be made when small or thin masses are joined to larger or thicker masses; at such places the use of fillets similar to those used in metal castings, but proportionally larger, is recommended.

Shrinkage cracks are likely to occur at points where fresh concrete is joined to that which is set, and hence in placing the concrete, construction joints should be made, as described in Chapter VI, Section 1, or, if possible, at points where joints would naturally occur in dimension-stone masonry.

3. FIRE-PROOFING.

Concrete, because incombustible and of a low rate of heat conductivity, is highly efficient and admirably adapted for fire-proofing purposes. This has been demonstrated by experience and tests.

The dehydration of concrete probably begins at about 500° Fahr. and is completed at about 900° Fahr., but experience indicates that the volatilization of the water absorbs heat from the surrounding mass, which, together with the resistance of the air cells, tends to increase the heat resistance of the concrete, so that the process of dehy-

dration is very much retarded. The concrete that is actually affected by fire and remains in position affords protection to that beneath it.

The thickness of the protective coating should be governed by the intensity and duration of a possible fire and the rate of heat conductivity of the concrete. The question of the rate of heat conductivity of concrete is one which requires further study and investigation before a definite rate for different classes of concrete can be fully established. However, for ordinary conditions, it is recommended that the metal be protected by a minimum of 2 in. of concrete on girders and columns, 1½ in. on beams, and 1 in. on floor-slabs.

Where fire-proofing is required, and not otherwise provided in monolithic concrete columns, it is recommended that the concrete to a depth of 1½ in. be considered as protective covering, and not included in the effective section.

The corners of columns, girders, and beams should be beveled or rounded, as a sharp corner is more seriously affected by fire than a round one; experience shows that round columns are more fire resistive than square.

4. WATER-PROOFING.

Many expedients have been resorted to for rendering concrete impervious to water. Experience shows, however, that when mortar or concrete is proportioned to obtain the greatest practicable density and is mixed to the proper consistency (Chapter IV, Section 2 *d*), the resulting mortar or concrete is impervious under moderate pressure.

On the other hand, concrete of dry consistency is more or less pervious to water, and, though compounds of various kinds have been mixed with the concrete or applied as a wash to the surface, in an effort to offset this defect, these expedients have generally been disappointing, for the reason that many of these compounds have at best but temporary value, and in time lose their power of imparting impermeability to the concrete.

In the case of subways, long retaining walls and reservoirs, provided the concrete itself is impervious, cracks may be so reduced, by horizontal and vertical reinforcement properly proportioned and located, that they will be too minute to permit leakage, or will be closed by infiltration of silt.

Asphaltic or coal-tar preparations applied either as a mastic or as a coating on felt or cloth fabric, are used for water-proofing, and should be proof against injury by liquids or gases.

For retaining and similar walls in direct contact with the earth, the application of one or two coatings of hot coal-tar pitch, following a painting with a thin wash of coal tar dissolved in benzol, to the thoroughly dried surface of concrete is an efficient method of preventing the penetration of moisture from the earth.

5. SURFACE FINISH.

Concrete is a material of an individual type, and should be used without effort at imitation of other building materials. One of the important problems connected with its use is the character of the finish of exposed surfaces. The desired finish should be determined before the concrete is placed, and the work conducted so as to facilitate securing it. The natural surface of the concrete in most structures is unobjectionable, but in others the marks of the forms and the flat dead surface are displeasing, making some special treatment desirable. A treatment of the surface which removes the film of cement and brings the aggregates of the concrete into relief, either by scrubbing with brushes and water before it is hard, or by tooling it after it is hard, is frequently used to erase the form markings and break the monotonous appearance of the surface. Besides being more pleasing in immediate appearance, such a surface is less subject to discoloration and hair cracking than is a surface composed of the cement that segregates against the forms, or one that is made by applying a cement wash. The aggregates can also be exposed by washing with hydrochloric acid diluted with from 6 to 10 parts of water. The plastering of surfaces should be avoided, for even if carefully done, it is liable to peel off under the action of frost or temperature changes.

Various effects in texture and in color can be obtained when the surface is to be scrubbed or tooled, by using aggregates of the desired size and color. For a fine-grained texture a granolithic surface mixture can be made and placed against the face forms to a thickness of about 1 in. as the placing of the body of the concrete proceeds.

A smooth, even surface without form marks can be secured by the use of plastered forms, which, in structures having many duplications of members, can be used repeatedly; these are made in panels of expanded metal or wire mesh coated with plaster, and the joints made at edges, and closed with plaster of Paris.

CHAPTER VII.

DESIGN.

1. MASSIVE CONCRETE.

In the design of massive or plain concrete, no account should be taken of the tensile strength of the material, and sections should usually be proportioned so as to avoid tensile stresses except in slight amounts to resist indirect stresses. This will generally be accomplished in the case of rectangular shapes if the line of pressure is kept within the middle third of the section, but in very large structures, such as high masonry dams, a more exact analysis may be required. Structures of massive concrete are able to resist unbalanced lateral

forces by reason of their weight; hence the element of weight rather than strength often determines the design. A leaner and relatively cheap concrete, therefore, will often be suitable for massive concrete structures.

It is desirable generally to provide joints at intervals to localize the effect of contraction (Chapter VI, Section 1).

Massive concrete is suitable for dams, retaining walls, and piers in which the ratio of leugth to least width is relatively small. Under ordinary conditions, this ratio should not exceed four. It is also suitable for arches of moderate span.

2. REINFORCED CONCRETE.

The use of metal reinforcement is particularly advantageous in members such as beams in which both tension and compression exist, and in columns where the principal stresses are compressive and where there also may be cross-bending. Therefore the theory of design here presented relates mainly to the analysis of beams and columns.

3. GENERAL ASSUMPTIONS.

(*a*) *Loads.*—The forces to be resisted are those due to:

1. *The dead load,* which includes the weight of the structure and fixed loads and forces.
2. *The live load,* or the loads and forces which are variable. The dynamic effect of the live load will often require consideration. Allowance for the latter is preferably made by a proportionate increase in either the live load or the live-load stresses. The working stresses hereinafter recommended are intended to apply to the equivalent static stresses thus determined.

   In the case of high buildings, the live load on columns may be reduced in accordance with the usual practice.

(*b*) *Lengths of Beams and Columns.*—The span length for beams and slabs simply supported should be taken as the distance from center to center of supports, but need not be taken to exceed the clear span plus the depth of beam or slab. For continuous or restrained beams built monolithically into supports, the span length may be taken as the clear distance between faces of supports. Brackets should not be considered as reducing the clear span in the sense here intended, except that when brackets which make an angle of 45° or more with the axis of a restrained beam are built monolithically with the beam, the span may be measured from the section where the combined depth of beam and bracket is at least one-third more than the depth of the beam. Maximum negative moments are to be considered as existing at the end of the span as here defined.

When the depth of a restrained beam is greater at its ends than at mid-span and the slope of the bottom of the beam at its ends makes an angle of not more than 15° with the direction of the axis of the beam at mid-span, the span length may be measured from face to face of supports.

The length of columns should be taken as the maximum unstayed length.

(*c*) *Stresses.*—The following assumptions are recommended as a basis for calculations:

1. Calculations will be made with reference to working stresses and safe loads, rather than with reference to ultimate strength and ultimate loads.
2. A plane section before bending remains plane after bending.
3. The modulus of elasticity of concrete in compression is constant within the usual limits of working stresses. The distribution of compressive stress in beams is therefore rectilinear.
4. In calculating the moment of resistance of beams, the tensile stresses in the concrete are neglected.
5. The adhesion between the concrete and the reinforcement is perfect. Under compressive stress the two materials are therefore stressed in proportion to their moduli of elasticity.
6. The ratio of the modulus of elasticity of steel to the modulus of elasticity of concrete is taken at 15 except as modified in Chapter VIII, Section 8.
7. Initial stress in the reinforcement due to contraction or expansion of the concrete is neglected.

It is recognized that some of the assumptions given herein are not entirely borne out by experimental data. They are given in the interest of simplicity and uniformity, and variations from exact conditions are taken into account in the selection of formulas and working stresses.

The deflection of a beam depends upon the strength and stiffness developed throughout its length. For calculating deflection, a value of 8 for the ratio of the moduli will give results corresponding approximately with the actual conditions.

4. T-BEAMS.

In beam and slab construction an effective bond should be provided at the junction of the beam and slab. When the principal slab reinforcement is parallel to the beam, transverse reinforcement should be used, extending over the beam and well into the slab.

The slab may be considered an integral part of the beam, when adequate bond and shearing resistance between slab and web of beam is provided, but its effective width shall be determined by the following rules:

(*a*) It shall not exceed one-fourth of the span length of the beam;

(*b*) Its overhanging width on either side of the web shall not exceed six times the thickness of the slab.

In the design of continuous T-beams, due consideration should be given to the compressive stress at the support.

Beams in which the T-form is used only for the purpose of providing additional compression area of concrete should preferably have a width of flange not more than three times the width of the stem and a thickness of flange not less than one-third of the depth of the beam. Both in this form and in the beam and slab form the web stresses and the limitations in placing and spacing the longitudinal reinforcement will probably be controlling factors in design.

5. FLOOR-SLABS SUPPORTED ALONG FOUR SIDES.

Floor-slabs having the supports extending along the four sides should be designed and reinforced as continuous over the supports. If the length of the slab exceeds one and one-half times its width, the entire load should be carried by transverse reinforcement.

For uniformly distributed loads on square slabs, one-half the live and dead load may be used in the calculations of moment to be resisted in each direction. For oblong slabs, the length of which is not greater than one and one-half times their width, the moment to be resisted by the transverse reinforcement may be found by using a proportion of the live and dead load equal to that given by the formula, $r = \frac{l}{b} - 0.5$, where l = length and b = breadth of slab. The longitudinal reinforcement should then be proportioned to carry the remainder of the load.

In placing reinforcement in such slabs account may well be taken of the fact that the bending moment is greater near the center of the slab than near the edges. For this purpose two-thirds of the previously calculated moments may be assumed as carried by the center half of the slab and one-third by the outside quarters.

Loads carried to beams by slabs which are reinforced in two directions will not be uniformly distributed to the supporting beams, and the distribution will depend on the relative stiffness of the slab and the supporting beams. The distribution which may be expected ordinarily is a variation of the load in the beam in accordance with

the ordinates of a parabola, having its vertex at the middle of the span. For any given design, the probable distribution should be ascertained and the moments in the beam calculated accordingly.

6. CONTINUOUS BEAMS AND SLABS.

When the beam or slab is continuous over its supports, reinforcement should be fully provided at points of negative moment, and the stresses in concrete recommended in Chapter VIII, Section 4, should not be exceeded. In computing the positive and negative moments in beams and slabs continuous over several supports, due to uniformly distributed loads, the following rules are recommended:

(*a*) For floor-slabs, the bending moments at center and at support should be taken at $\frac{wl^2}{12}$ for both dead and live loads, where w represents the load per linear unit and l the span length.

(*b*) For beams, the bending moment at center and at support for interior spans should be taken at $\frac{wl^2}{12}$ and for end spans it should be taken at $\frac{wl^2}{10}$ for center and interior support, for both dead and live loads.

(*c*) In the case of beams and slabs continuous for two spans only, with their ends restrained, the bending moment both at the central support and near the middle of the span should be taken as $\frac{wl^2}{10}$.

(*d*) At the ends of continuous beams, the amount of negative moment which will be developed in the beam will depend on the condition of restraint or fixedness, and this will depend on the form of construction used. In the ordinary cases a moment of $\frac{wl^2}{16}$ may be taken; for small beams running into heavy columns this should be increased, but not to exceed $\frac{wl^2}{12}$.

For spans of unusual length, or for spans of materially unequal length, more exact calculations should be made. Special consideration is also required in the case of concentrated loads.

Even if the center of the span is designed for a greater bending moment than is called for by (*a*) or (*b*), the negative moment at the support should not be taken as less than the values there given.

Where beams are reinforced on the compression side, the steel may be assumed to carry its proportion of stress in accordance with the ratio of moduli of elasticity, Chapter VIII, Section 8. Reinforcing bars for compression in beams should be straight and should be two diameters in the clear from the surface of the concrete. For the positive bending moment, such reinforcement should not exceed 1% of the area of the concrete. In the case of cantilever and continuous beams, tensile and compressive reinforcement over supports should extend sufficiently beyond the support and beyond the point of inflection to develop the requisite bond strength.

In construction made continuous over supports, it is important that ample foundations should be provided; for unequal settlements are liable to produce unsightly if not dangerous cracks. This effect is more likely to occur in low structures.

Girders, such as wall girders, which have beams framed into one side only, should be designed to resist torsional moment arising from the negative moment at the end of the beam.

7. BOND STRENGTH AND SPACING OF REINFORCEMENT.

Adequate bond strength should be provided. The formula hereinafter given for bond stresses in beams is for straight longitudinal bars. In beams in which a portion of the reinforcement is bent up near the end, the bond stress at places, in both the straight bars and the bent bars, will be considerably greater than for all the bars straight, and the stress at some point may be several times as much as that found by considering the stress to be uniformly distributed along the bar. In restrained and cantilever beams, full tensile stress exists in the reinforcing bars at the point of support, and the bars should be anchored in the support sufficiently to develop this stress.

In case of anchorage of bars, an additional length of bar should be provided beyond that found on the assumption of uniform bond stress, for the reason that before the bond resistance at the end of the bar can be developed the bar may have begun to slip at another point, and "running" resistance is less than the resistance before slip begins.

Where high bond resistance is required, the deformed bar is a suitable means of supplying the necessary strength. But it should be recognized that, even with a deformed bar, initial slip occurs at early loads, and that the ultimate loads obtained in the usual tests for bond resistance may be misleading. Adequate bond strength throughout the length of a bar is preferable to end anchorage, but, as an additional safeguard, such anchorage may properly be used in special cases. Anchorage furnished by short bends at a right angle is less effective than by hooks consisting of turns through 180 degrees.

The lateral spacing of parallel bars should be not less than three diameters from center to center, nor should the distance from the side of the beam to the center of the nearest bar be less than two diameters. The clear spacing between two layers of bars should be not less than 1 in. The use of more than two layers is not recommended, unless the layers are tied together by adequate metal connections, particularly at and near points where bars are bent up or bent down. Where more than one layer is used, at least all bars above the lower layer should be bent up and anchored beyond the edge of the support.

8. DIAGONAL TENSION AND SHEAR.

When a reinforced concrete beam is subjected to flexural action, diagonal tensile stresses are set up. A beam without web reinforcement will fail if these stresses exceed the tensile strength of the concrete. When web reinforcement, made up of stirrups or of diagonal bars secured to the longitudinal reinforcement, or of longitudinal reinforcing bars bent up at several points, is used, new conditions prevail, but, even in this case, at the beginning of loading the diagonal tension developed is taken principally by the concrete, the deformations which are developed in the concrete permitting but little stress to be taken by the web reinforcement. When the resistance of the concrete to the diagonal tension is overcome at any point in the depth of the beam, greater stress is at once set up in the web reinforcement.

For homogeneous beams, the analytical treatment of diagonal tension is not very complex—the diagonal tensile stress is a function of the horizontal and vertical shearing stresses and of the horizontal tensile stress at the point considered, and as the intensity of these three stresses varies from the neutral axis to the remotest fiber, the intensity of the diagonal tension will be different at different points in the section, and will change with different proportionate dimensions of length to depth of beam. For the composite structure of reinforced concrete beams, an analysis of the web stresses, and particularly of the diagonal tensile stresses, is very complex; and when the variations due to a change from no horizontal tensile stress in the concrete at remotest fiber to the presence of horizontal tensile stress at some point below the neutral axis are considered, the problem becomes more complex and indefinite. Under these circumstances, in designing, recourse is had to the use of the calculated vertical shearing stress, as a means of comparing or measuring the diagonal tensile stresses developed, it being understood that the vertical shearing stress is not the numerical equivalent of the diagonal tensile stress, and that there is not even a constant ratio between them. It is here recommended that the maximum vertical shearing stress in a section be used as the means of

comparison of the resistance to diagonal tensile stress developed in the concrete in beams not having web reinforcement.

Even after the concrete has reached its limit of resistance to diagonal tension, if the beam has web reinforcement, conditions of beam action will continue to prevail, at least through the compression area, and the web reinforcement will be called on to resist only a part of the web stresses. From experiments with beams it is concluded that it is safe practice to use only two-thirds of the external vertical shear in making calculations of the stresses that come on stirrups, diagonal web pieces, and bent-up bars, and it is here recommended for calculations in designing that two-thirds of the external vertical shear be taken as producing stresses in web reinforcement.

It is well established that vertical members attached to or looped about horizontal members, inclined members secured to horizontal members in such a way as to insure against slip, and the bending of a part of the longitudinal reinforcement at an angle, will increase the strength of a beam against failure by diagonal tension, and that a well-designed and well-distributed web reinforcement may, under the best conditions, increase the total vertical shear carried to a value as much as three times that obtained when the bars are all horizontal and no web reinforcement is used.

When web reinforcement comes into action as the principal tension web resistance, the bond stresses between the longitudinal bars and the concrete are not distributed as uniformly along the bars as they otherwise would be, but tend to be concentrated at and near stirrups, and at and near the points where bars are bent up. When stirrups are not rigidly attached to the longitudinal bars, and the proportioning of bars and stirrup spacing is such that local slip of bars occur at stirrups, the effectiveness of the stirrups is impaired, though the presence of stirrups still gives an element of toughness against diagonal tension failure.

Sufficient bond resistance between the concrete and the stirrups or diagonals must be provided in the compression area of the beam.

The longitudinal spacing of vertical stirrups should not exceed one-half the depth of beam, and that of inclined members should not exceed three-fourths of the depth of beam.

Bending of longitudinal reinforcing bars at an angle across the web of the beam may be considered as adding to diagonal tension resistance for a horizontal distance from the point of bending equal to three-fourths of the depth of beam. Where the bending is made at two or more points, the distance between points of bending should not exceed three-fourths of the depth of the beam. In the case of a restrained beam, the effect of bending up a bar at the bottom of the beam in resisting diagonal tension may not be taken as extending

beyond a section at the point of inflection, and the effect of bending down a bar in the region of negative moment may be taken as extending from the point of bending down of bar nearest the support to a section not more than three-fourths of the depth of beam beyond the point of bending down of bar farthest from the support, but not beyond the point of inflection. In case stirrups are used in the beam away from the region in which the bent bars are considered effective, a stirrup should be placed not farther than a distance equal to one-fourth the depth of beam from the limiting sections defined above. In case the web resistance required through the region of bent bars is greater than that furnished by the bent bars, sufficient additional web reinforcement in the form of stirrups or attached diagonals should be provided. The higher resistance to diagonal tension stresses given by unit frames having the stirrups and bent-up bars securely connected together both longitudinally and laterally is worthy of recognition. It is necessary that a limit be placed on the amount of shear which may be allowed in a beam; for when web reinforcement sufficiently efficient to give very high web resistance is used, at the higher stresses the concrete in the beam becomes checked and cracked in such a way as to endanger its durability as well as its strength.

The section to be taken as the critical section in the calculation of shearing stresses will generally be the one having the maximum vertical shear, though experiments show that the section at which diagonal tension failures occur is not just at a support, even though the shear at the latter point be much greater.

In the case of restrained beams, the first stirrup or the point of bending down of bar should be placed not farther than one-half of the depth of beam away from the face of the support.

It is important that adequate bond strength or anchorage be provided to develop fully the assumed strength of all web reinforcement.

Low bond stresses in the longitudinal bars are helpful in giving resistance against diagonal tension failures, and anchorage of longitudinal bars at the ends of the beams or in the supports is advantageous.

It should be noted that it is on the tension side of a beam that diagonal tension develops in a critical way, and that proper connection should always be made between stirrups or other web reinforcement and the longitudinal tension reinforcement, whether the latter is on the lower side of the beam or on its upper side. Where negative moment exists, as is the case near the supports in a continuous beam, web reinforcement, to be effective, must be looped over or wrapped around, or be connected with, the longitudinal tension reinforcing bars at the top of the beam in the same way as is necessary at the bottom of the beam at sections where the bending moment is positive.

Inasmuch as the smaller the longitudinal deformations in the

horizontal reinforcement are, the less the tendency for the formation of diagonal cracks, a beam will be strengthened against diagonal tension failure by so arranging and proportioning the horizontal reinforcement that the unit stresses at points of large shear shall be relatively low.

It does not seem feasible to make a complete analysis of the action of web reinforcement, and more or less empirical methods of calculation are therefore employed. Limiting values of working stresses for different types of web reinforcement are given in Chapter VIII, Section 5. The conditions apply to cases commonly met in design. It is assumed that adequate bond resistance or anchorage of all web reinforcement will be provided.

When a flat slab rests on a column, or a column bears on a footing, the vertical shearing stresses in the slab or footing immediately adjacent to the column are termed punching shearing stresses. The element of diagonal tension, being a function of the bending moment as well as of shear, may be small in such cases, or may be otherwise provided for. For this reason the permissible limit of stress for punching shear may be higher than the allowable limit when the shearing stress is used as a means of comparing diagonal tensile stress. The working values recommended are given in Chapter VIII, Section 5.

9. COLUMNS.

By columns are meant compression members of which the ratio of unsupported length to least width exceeds about four, and which are provided with reinforcement of one of the forms hereafter described.

It is recommended that the ratio of unsupported length of column to its least width be limited to 15.

The effective area of hooped columns or columns reinforced with structural shapes shall be taken as the area within the circle enclosing the spiral or the polygon enclosing the structural shapes.

Columns may be reinforced by longitudinal bars; by bands, hoops, or spirals, together with longitudinal bars; or by structural forms which are sufficiently rigid to have value in themselves as columns. The general effect of closely spaced hooping is to greatly increase the toughness of the column and to add to its ultimate strength, but hooping has little effect on its behavior within the limit of elasticity. It thus renders the concrete a safer and more reliable material, and should permit the use of a somewhat higher working stress. The beneficial effects of toughening are adequately provided by a moderate amount of hooping, a larger amount serving mainly to increase the ultimate strength and the deformation possible before ultimate failure.

Composite columns of structural steel and concrete, in which the steel forms a column by itself, should be designed with caution. To classify this type as a concrete column reinforced with structural

steel is hardly permissible, as the steel generally will take the greater part of the load. When this type of column is used, the concrete should not be relied upon to tie the steel units together nor to transmit stresses from one unit to another. The units should be adequately tied together by tie-plates or lattice bars, which, together with other details, such as splices, etc., should be designed in conformity with standard practice for structural steel. The concrete may exert a beneficial effect in restraining the steel from lateral deflection and also in increasing the carrying capacity of the column. The proportion of load to be carried by the concrete will depend on the form of the column and the method of construction. Generally, for high percentages of steel, the concrete will develop relatively low unit stresses, and caution should be used in placing dependence on the concrete.

The following recommendations are made for the relative working stresses in the concrete for the several types of columns:

(*a*) Columns with longitudinal reinforcement to the extent of not less than 1% and not more than 4%, and with lateral ties of not less than ¼ in. in diameter, 12 in. apart, nor more than 16 diameters of the longitudinal bar: the unit stress recommended for axial compression, on concrete piers having a length not more than four diameters, in Chapter VIII, Section 3.

(*b*) Columns reinforced with not less than 1% and not more than 4% of longitudinal bars and with circular hoops or spirals not less than 1% of the volume of the concrete and as hereinafter specified: a unit stress 55% higher than given for (*a*), provided the ratio of unsupported length of column to diameter of the hooped core is not more than 10.

The foregoing recommendations are based on the following conditions:

It is recommended that the minimum size of columns to which the working stresses may be applied be 12 in., out to out.

In all cases longitudinal reinforcement is assumed to carry its proportion of stress in accordance with Section 3 (*c*) 6 of this chapter. The hoops or bands are not to be counted on directly as adding to the strength of the column.

Longitudinal reinforcement bars should be maintained straight, and shall have sufficient lateral support to be securely held in place until the concrete has set.

Where hooping is used, the total amount of such reinforcement shall be not less than 1% of the volume of the column, enclosed. The clear spacing of such hooping shall be not greater than one-sixth the diameter of the enclosed column, and preferably not greater than one-

tenth, and in no case more than $2\frac{1}{2}$ in. Hooping is to be circular and the ends of bands must be united in such a way as to develop their full strength. Adequate means must be provided to hold bands or hoops in place so as to form a column, the core of which shall be straight and well centered. The strength of hooped columns depends very much upon the ratio of length to diameter of hooped core, and the strength due to hooping decreases rapidly as this ratio increases beyond five. The working stresses recommended are for hooped columns with a length of not more than ten diameters of the hooped core. The Committee has no recommendation to make for a formula for working stresses for columns longer than ten diameters.

Bending stresses due to eccentric loads, such as unequal spans of beams, and to lateral forces, must be provided for by increasing the section until the maximum stress does not exceed the values above specified. Where tension is possible in the longitudinal bars of the column, adequate connection between the ends of the bars must be provided to take this tension.

10. REINFORCING FOR SHRINKAGE AND TEMPERATURE STRESSES.

When areas of concrete too large to expand and contract freely as a whole are exposed to atmospheric conditions, the changes of form due to shrinkage and to action of temperature are such that cracks may occur in the mass unless precautions are taken to distribute the stresses so as to prevent the cracks altogether or to render them very small. The distance apart of the cracks, and consequently their size, will be directly proportional to the diameter of the reinforcement and to the tensile strength of the concrete, and inversely proportional to the percentage of reinforcement and also to its bond resistance per unit of surface area. To be most effective, therefore, reinforcement (in amount generally not less than one-third of 1% of the gross area) of a form which will develop a high bond resistance should be placed near the exposed surface and be well distributed. Where openings occur the area of cross-section of the reinforcement should not be reduced. The allowable size and spacing of cracks depends on various considerations, such as the necessity for water-tightness, the importance of appearance of the surface, and the atmospheric changes.

The tendency of concrete to shrink makes it necessary, except where expansion is provided for, to thoroughly connect the component parts of the frame of articulated structures, such as floor and wall members in buildings, by the use of suitable reinforcing material. The amount of reinforcement for such connection should bear some relation to the size of the members connected, larger and heavier members requiring stronger connections. The reinforcing bars should be extended beyond the critical section far enough, or should be sufficiently anchored to develop their full tensile strength.

11. FLAT SLAB.

The continuous flat slab reinforced in two or more directions and built monolithically with the supporting columns (without beams or girders) is a type of construction which is now extensively used and which has recognized advantages for certain types of structures as, for example, warehouses in which large, open floor space is desired. In its construction, there is excellent opportunity for inspecting the position of the reinforcement. The conditions attending depositing and placing of concrete are favorable to securing uniformity and soundness in the concrete. The recommendations in the following paragraphs relate to flat slabs extending over several rows of panels in each direction. Necessarily the treatment is more or less empirical.

The coefficients and moments given relate to uniformly distributed loads.

(*a*) *Column Capital.*—It is usual in flat slab construction to enlarge the supporting columns at their top, thus forming column capitals. The size and shape of the column capital affect the strength of the structure in several ways. The moment of the external forces which the slab is called upon to resist is dependent upon the size of the capital; the section of the slab immediately above the upper periphery of the capital carries the highest amount of punching shear; and the bending moment developed in the column by an eccentric or unbalanced loading of the slab is greatest at the under surface of the slab. Generally, the horizontal section of the column capital should be round or square with rounded corners. In oblong panels the section may be oval or oblong, with dimensions proportional to the panel dimensions. For computation purposes, the diameter of the column capital will be considered to be measured where its vertical thickness is at least $1\frac{1}{2}$ in., provided the slope of the capital below this point nowhere makes an angle with the vertical of more than 45 degrees. In case a cap is placed above the column capital, the part of this cap within a cone made by extending the lines of the column capital upward at the slope of 45° to the bottom of the slab or dropped panel may be considered as part of the column capital in determining the diameter for design purposes. Without attempting to limit the size of the column capital for special cases, it is recommended that the diameter of the column capital (or its dimension parallel to the edge of the panel) generally be made not less than one-fifth of the dimension of the panel from center to center of adjacent columns. A diameter equal to 0.225 of the panel length has been used quite widely and acceptably. For heavy loads or large panels, especial attention should be given to designing and reinforcing the column capital with respect to compressive stresses and bending moments. In the case of heavy loads or large panels, and where the conditions of the panel loading

or variations in panel length or other conditions cause high bending stresses in the column, and also for column capitals smaller than the size herein recommended, especial attention should be given to designing and reinforcing the column capital with respect to compression and to rigidity of connection to floor-slab.

(*b*) *Dropped Panel.*—In one type of construction the slab is thickened throughout an area surrounding the column capital. The square or oblong of thickened slab thus formed is called a dropped panel or a drop. The thickness and the width of the dropped panel may be governed by the amount of resisting moment to be provided (the compressive stress in the concrete being dependent upon both thickness and width), or its thickness may be governed by the resistance to shear required at the edge of the column capital and its width by the allowable compressive stresses and shearing stresses in the thinner portion of the slab adjacent to the dropped panel. Generally, however, it is recommended that the width of the dropped panel be at least four-tenths of the corresponding side of the panel as measured from center to center of columns, and that the offset in thickness be not more than five-tenths of the thickness of the slab outside the dropped panel.

(*c*) *Slab Thickness.*—In the design of a slab, the resistance to bending and to shearing forces will largely govern the thickness, and, in the case of large panels with light loads, resistance to deflection may be a controlling factor. The following formulas for minimum thicknesses are recommended as general rules of design when the diameter of the column capital is not less than one-fifth of the dimension of the panel from center to center of adjacent columns, the larger dimension being used in the case of oblong panels. For notation, let

t = total thickness of slab, in inches;
L = panel length, in feet;
w = sum of live load and dead load, in pounds per square foot.

Then, for a slab without dropped panels,

$$\text{minimum } t = 0.024\ L\ \sqrt{w} + 1\tfrac{1}{2};$$

for a slab with dropped panels,

$$\text{minimum } t = 0.02\ L\ \sqrt{w} + 1;$$

for a dropped panel whose width is four-tenths of the panel length,

$$\text{minimum } t = 0.03\ L\ \sqrt{w} + 1\tfrac{1}{2}.$$

In no case should the slab thickness be made less than 6 in., nor should the thickness of a floor-slab be made less than one-thirty-second of the panel length, nor the thickness of a roof slab less than one-fortieth of the panel length.

(*d*) *Bending and Resisting Moments in Slabs.*—If a vertical section of a slab be taken across a panel along a line midway between columns, and if another section be taken along an edge of the panel parallel to the first section, but skirting the part of the periphery of the column capitals at the two corners of the panels, the moment of the couple formed by the external load on the half panel, exclusive of that over the column capital (sum of dead and live loads) and the resultant of the external shear or reaction at the support at the two column capitals (see Fig. 1), may be found by ordinary static analysis. It will be noted that the edges of the area here considered are along lines of zero shear, except around the column capitals. This moment of the external forces acting on the half panel will be resisted by the numerical sum of (*a*) the moment of the internal stresses at the section of the panel midway between columns (positive resisting moment)

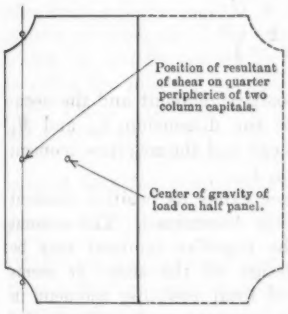

FIG. 1.

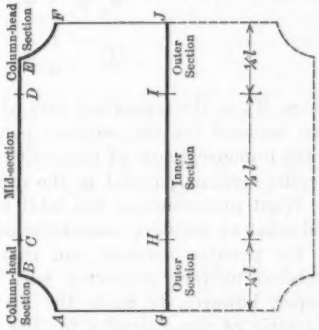

FIG. 2.

and (*b*) the moment of the internal stresses at the section referred to at the end of the panel (negative resisting moment). In the curved portion of the end section (that skirting the column), the stresses considered are the components which act parallel to the normal stresses on the straight portion of the section. Analysis shows that, for a uniformly distributed load, and round columns, and square panels, the numerical sum of the positive moment and the negative moment at the two sections named is given quite closely by the equation

$$M_s = \frac{1}{8}\ wl\ \left(l - \frac{2}{3}\,c\right)^2.$$

In this formula and in those which follow relating to oblong panels,

w = Sum of the live and dead loads per unit of area;

l = Side of a square panel measured from center to center of columns;

l_1 = One side of the oblong panel measured from center to center of columns;

l_2 = Other side of oblong panel measured in the same way;
c = Diameter of the column capital;
M_x = Numerical sum of positive moment and negative moment in one direction;
M_y = Numerical sum of positive moment and negative moment in the other direction.

(See paper and closure, "Statical Limitations upon the Steel Requirement in Reinforced Concrete Flat Slab Floors", by John R. Nichols, Jun. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXVII.)

For oblong panels, the equation for the numerical sum of the positive moment and the negative moment at the two sections named becomes

$$M_x = \frac{1}{8} wl_2 \left(l_1 - \frac{2}{3} c\right)^2$$

$$M_y = \frac{1}{8} wl_1 \left(l_2 - \frac{2}{3} c\right)^2$$

where M_x is the numerical sum of the positive moment and the negative moment for the sections parallel to the dimension, l_2, and M_y is the numerical sum of the positive moment and the negative moment for the sections parallel to the dimension, l_1.

What proportion of the total resistance exists as positive moment and what as negative moment is not readily determined. The amount of the positive moment and that of the negative moment may be expected to vary somewhat with the design of the slab. It seems proper, however, to make the division of total resisting moment in the ratio of three-eighths for the positive moment to five-eighths for the negative moment.

With reference to variations in stress along the sections, it is evident from conditions of flexure that the resisting moment is not distributed uniformly along either the section of positive moment or that of negative moment. As the law of the distribution is not known definitely, it will be necessary to make an empirical apportionment along the sections; and it will be considered sufficiently accurate generally to divide the sections into two parts and to use an average value over each part of the panel section.

The relatively large breadth of structure in a flat slab makes the effect of local variations in the concrete less than would be the case for narrow members like beams. The tensile resistance of the concrete is less affected by cracks. Measurements of deformations in buildings under heavy load indicate the presence of considerable tensile resistance in the concrete, and the presence of this tensile resistance acts to decrease the intensity of the compressive stresses. It is believed that the use of moment coefficients somewhat less than those given in a preceding

paragraph as derived by analysis is warranted, the calculations of resisting moment and stresses in concrete and reinforcement being made according to the assumptions specified in this report and no change being made in the values of the working stresses ordinarily used. Accordingly, the values of the moments which are recommended for use are somewhat less than those derived by analysis. The values given may be used when the column capitals are round, oval, square, or oblong.

(*e*) *Names for Moment Sections.*—For convenience, that portion of the section across a panel along a line midway between columns which lies within the middle two quarters of the width of the panel (*HI*, Fig. 2) will be called the inner section, and that portion in the two outer quarters of the width of the panel (*GH* and *IJ*, Fig. 2) will be called the outer sections. Of the section which follows a panel edge from column capital to column capital and which includes the quarter peripheries of the edges of two column capitals, that portion within the middle two quarters of the panel width (*CD*, Fig. 2) will be called the mid-section, and the two remaining portions (*ABC* and *DEF*, Fig. 2), each having a projected width equal to one-fourth of the panel width, will be called the column-head sections.

(*f*) *Positive Moment.*—For a square interior panel, it is recommended that the positive moment for a section in the middle of a panel extending across its width be taken as $\frac{1}{25} wl \left(l - \frac{2}{3} c\right)^2$. Of this moment, at least 25% should be provided for in the inner section; in the two outer sections of the panel at least 55% of the specified moment should be provided for in slabs not having dropped panels, and at least 60% in slabs having dropped panels, except that in calculations to determine necessary thickness of slab away from the dropped panel at least 70% of the positive moment should be considered as acting in the two outer sections.

(*g*) *Negative Moment.*—For a square interior panel, it is recommended that the negative moment for a section which follows a panel edge from column capital to column capital and which includes the quarter peripheries of the edges of the two column capitals (the section altogether forming the projected width of the panel) be taken as $\frac{1}{15} wl \left(l - \frac{2}{3} c\right)^2$. Of this negative moment, at least 20% should be provided for in the mid-section and at least 65% in the two column-head sections of the panel, except that in slabs having dropped panels at least 80% of the specified negative moment should be provided for in the two column-head sections of the panel.

(*h*) *Moments for Oblong Panels.*—When the length of a panel does not exceed the breadth by more than 5%, computation may be made

on the basis of a square panel with sides equal to the mean of the length and the breadth.

When the long side of an interior oblong panel exceeds the short side by more than one-twentieth and by not more than one-third of the short side, it is recommended that the positive moment be taken as $\frac{1}{25} wl_2 \left(l_1 - \frac{2}{3} c\right)^2$ on a section parallel to the dimension, l_2, and $\frac{1}{25} wl_1 \left(l_2 - \frac{2}{3} c\right)^2$ on a section parallel to the dimension, l_1; and that the negative moment be taken as $\frac{1}{15} wl_2 \left(l_1 - \frac{2}{3} c\right)^2$ on a section at the edge of the panel corresponding to the dimension, l_2, and $\frac{1}{15} wl_1 \left(l_2 - \frac{2}{3} c\right)^2$ at a section in the other direction. The limitations of the apportionment of moment between inner section and outer section and between mid-section and column-head sections may be the same as for square panels.

(*i*) *Wall Panels.*—The coefficient of negative moment at the first row of columns away from the wall should be increased 20% over that required for interior panels, and likewise the coefficient of positive moment at the section half way to the wall should be increased by 20 per cent. If girders are not provided along the wall, or the slab does not project as a cantilever beyond the column line, the reinforcement parallel to the wall for the negative moment in the column-head section and for the positive moment in the outer section should be increased by 20 per cent. If the wall is carried by the slab, this concentrated load should be provided for in the design of the slab. The coefficient of negative moments at the wall to take bending in the direction perpendicular to the wall line may be determined by the conditions of restraint and fixedness as found from the relative stiffness of columns and slab, but in no case should it be taken as less than one-half of that for interior panels.

(*j*) *Reinforcement.*—In the calculation of moments, all the reinforcing bars which cross the section under consideration and which fulfill the requirements given under Paragraph (*l*) of this chapter may be used. For a column-head section, reinforcing bars parallel to the straight portion of the section do not contribute to the negative resisting moment for the column-head section in question. In the case of four-way reinforcement, the sectional area of the diagonal bars multiplied by the sine of the angle between the diagonal of the panel and the straight portion of the section under consideration may be taken to act as reinforcement in a rectangular direction.

(*k*) *Point of Inflection.*—For the purpose of making calculations of moments at sections away from the sections of negative moment

and positive moment already specified, the point of inflection on any line parallel to a panel edge may be taken as one-fifth of the clear distance on that line between the two sections of negative moment at the opposite ends of the panel indicated in Paragraph (*e*) of this chapter. For slabs having dropped panels, the coefficient of one-fourth should be used instead of one-fifth.

(*l*) *Arrangement of Reinforcement.*—The design should include adequate provision for securing the reinforcement in place, so as to take, not only the maximum moments, but the moments at intermediate sections. All bars in rectangular bands or diagonal bands should extend on each side of a section of maximum moment, either positive or negative, to points at least twenty diameters beyond the point of inflection, as defined herein, or be hooked or anchored at the point of inflection. In addition to this provision, bars in diagonal bands used as reinforcement for negative moment should extend on each side of a line drawn through the column center at right angles to the direction of the band at least a distance equal to thirty-five one-hundredths of the panel length, and bars in diagonal bands used as reinforcement for positive moment should extend on each side of a diagonal through the center of the panel at least a distance equal to thirty-five one-hundredths of the panel length; and no splice by lapping should be permitted at or near regions of maximum stress, except as just described. Continuity of reinforcing bars is considered to have advantages, and it is recommended that not more than one-third of the reinforcing bars in any direction be made of a length less than the distance center to center of columns in that direction. Continuous bars should not all be bent up at the same point of their length, but the zone in which this bending occurs should extend on each side of the assumed point of inflection, and should cover a width of at least one-fifteenth of the panel length. Mere draping of the bars should not be permitted. In four-way reinforcement, the position of the bars in both diagonal and rectangular directions may be considered in determining whether the width of zone of bending is sufficient.

(*m*) *Reinforcement at Construction Joints.*—It is recommended that at construction joints extra reinforcing bars equal in section to 20% of the amount necessary to meet the requirements for moments at the section where the joint is made be added to the reinforcement, these bars to extend not less than fifty diameters beyond the joint on each side.

(*n*) *Tensile and Compressive Stresses.*—The usual method of calculating the tensile and compressive stresses in the concrete and in the reinforcement, based on the assumptions for internal stresses given in this chapter, should be followed. In the case of the dropped panel, the section of the slab and dropped panel may be considered

to act integrally for a width equal to the width of the column-head section.

(*o*) *Provision for Diagonal Tension and Shear.*—In calculations for the shearing stress which is to be used as the means of measuring the resistance to diagonal tension stress, it is recommended that the total vertical shear on two column-head sections constituting a width equal to one-half the lateral dimension of the panel, for use in the formula for determining critical shearing stresses, be considered to be one-fourth of the total dead and live loads on a panel for a slab of uniform thickness, and to be three-tenths of the sum of the dead and live loads on a panel for a slab with dropped panels. The formula for shearing unit stress given in the Appendix to this report may then be written $v = \frac{0.25\ W}{b\,j\,d}$ for slabs of uniform thickness, and $v = \frac{0.30\ W}{b\,j\,d}$ for slabs with dropped panels, where W is the sum of the dead and live loads on a panel, b is half the lateral dimension of the panel measured from center to center of columns, and jd is the lever arm of the resisting couple at the section.

The calculation of what is commonly called punching shear may be made on the assumption of a uniform distribution over the section of the slab around the periphery of the column capital and also of a uniform distribution over the section of the slab around the periphery of the dropped panel, using in each case an amount of vertical shear greater by 25% than the total vertical shear on the section under consideration.

The values of working stresses should be those recommended for diagonal tension and shear in Chapter VIII, Section 5.

(*p*) *Walls and Openings.*—Girders or beams should be constructed to carry walls and other concentrated loads which are in excess of the working capacity of the slab. Beams should also be provided in case openings in the floor reduce the working strength of the slab below the required carrying capacity.

(*q*) *Unusual Panels.*—The coefficients, apportionments, and thicknesses recommended are for slabs which have several rows of panels in each direction, and in which the size of the panels is approximately the same. For structures having a width of one, two, or three panels, and also for slabs having panels of markedly different sizes, an analysis should be made of the moments developed in both slab and columns, and the values given herein modified accordingly. Slabs with paneled ceiling or with depressed paneling in the floor are to be considered as coming under the recommendations herein given.

(*r*) *Bending Moments in Columns.*—Provision should be made in both wall columns and interior columns for the bending moment which will be developed by unequally loaded panels, eccentric loading.

or uneven spacing of columns. The amount of moment to be taken by a column will depend upon the relative stiffness of columns and slab, and computations may be made by rational methods, such as the principle of least work, or of slope and deflection. Generally, the larger part of the unequalized negative moment will be transmitted to the columns, and the column should be designed to resist this bending moment. Especial attention should be given to wall columns and corner columns.

CHAPTER VIII.

Working Stresses.

1. General Assumptions.

The following working stresses are recommended for static loads. Proper allowances for vibration and impact are to be added to live loads where necessary to produce an equivalent static load before applying the unit stresses in proportioning parts.

In selecting the permissible working stress on concrete, the designer should be guided by the working stresses usually allowed for other materials of construction, so that all structures of the same class composed of different materials may have approximately the same degree of safety.

The following recommendations as to allowable stresses are given in the form of percentages of the ultimate strength of the particular concrete which is to be used; this ultimate strength is that developed at an age of 28 days, in cylinders 8 in. in diameter and 16 in. long, of the consistency described in Chapter IV, Section 2 (*d*), made and stored under laboratory conditions. In the absence of definite knowledge in advance of construction as to just what strength may be expected, the Committee submits the following values as those which should be obtained with materials and workmanship in accordance with the recommendations of this report.

Although occasional tests may show higher results than those here given, the Committee recommends that these values should be the maximum used in design.

Table of Compressive Strengths of Different Mixtures of Concrete.
(In Pounds per Square Inch.)

Aggregate	1:3*	1:4½*	1:6*	1:7½*	1:9*
Granite, trap rock	3 300	2 800	2 200	1 800	1 400
Gravel, hard limestone and hard sandstone	3 000	2 500	2 000	1 600	1 300
Soft limestone and sandstone	2 200	1 800	1 500	1 200	1 000
Cinders	800	700	600	500	400

Note.—For variations in the moduli of elasticity see Chapter VIII, Section 8.

* Combined volume fine and coarse aggregate measured separately.

2. BEARING.

When compression is applied to a surface of concrete of at least twice the loaded area, a stress of 35% of the compressive strength may be allowed in the area actually under load.

3. AXIAL COMPRESSION.

For concentric compression on a plain concrete pier, the length of which does not exceed four diameters, or on a column reinforced with longitudinal bars only, the length of which does not exceed twelve diameters, 22.5% of the compressive strength may be allowed.

For other forms of columns, the stresses obtained from the ratios given in Chapter VII, Section 9, may govern.

4. COMPRESSION IN EXTREME FIBER.

The extreme fiber stress of a beam, calculated on the assumption of a constant modulus of elasticity for concrete under working stresses may be allowed to reach 32.5% of the compressive strength. Adjacent to the support of continuous beams, stresses 15% higher may be used.

5. SHEAR AND DIAGONAL TENSION.

In calculations on beams in which the maximum shearing stress in a section is used as the means of measuring the resistance to diagonal tension stress, the following allowable values for the maximum vertical shearing stress in concrete, calculated by the method given in the Appendix, Formula 22, are recommended:

(*a*) For beams with horizontal bars only and without web reinforcement, 2% of the compressive strength.

(*b*) For beams with web reinforcement consisting of vertical stirrups looped about the longitudinal reinforcing bars in the tension side of the beam and spaced horizontally not more than one-half the depth of the beam; or for beams in which longitudinal bars are bent up at an angle of not more than 45° or less than 20° with the axis of the beam, and the points of bending are spaced horizontally not more than three-quarters of the depth of the beam apart, not to exceed 4½% of the compressive strength.

(*c*) For a combination of bent bars and vertical stirrups looped about the reinforcing bars in the tension side of the beam and spaced horizontally not more than one-half of the depth of the beam, 5% of the compressive strength.

(*d*) For beams with web reinforcement (either vertical or inclined) securely attached to the longitudinal bars in the tension side of the beam in such a way as to prevent slipping of bar past the stirrup, and spaced horizontally not more than one-half of the depth of the beam in case of vertical stirrups and not more than three-fourths of the depth of the beam in the case of inclined members.

either with longitudinal bars bent up or not, 6% of the compressive strength.

The web reinforcement in case any is used should be proportioned by using two-thirds of the external vertical shear in Formulas 24 or 25 in Chapter X. The effect of longitudinal bars bent up at an angle of from 20 to 45° with the axis of the beam, may be taken at sections of the beam in which the bent up bars contribute to diagonal tension resistance, as defined under Chapter VII, Section 8, as reducing the shearing stresses to be otherwise provided for. The amount of reduction of the shearing stress by means of bent up bars will depend upon their capacity, but in no case should be taken as greater than 4½% of the compressive strength of the concrete over the effective cross-section of the beam (Formula 22). The limit of tensile stress in the bent up portion of the bar calculated by Formula 25, using in this formula an amount of total shear corresponding to the reduction in shearing stress assumed for the bent up bars, may be taken as specified for the working stress of steel, but in the calculations the stress in the bar due to its part as longitudinal reinforcement of the beam should be considered. The stresses in stirrups and inclined members when combined with bent up bars are to be determined by finding the amount of the total shear which may be allowed by reason of the bent up bars, and subtracting this shear from the total external vertical shear. Two-thirds of the remainder will be the shear to be carried by the stirrups, using Formulas 24 or 25 in the Appendix.

Where punching shear occurs, provided the diagonal tension requirements are met, a shearing stress of 6% of the compressive strength may be allowed.

6. BOND.

The bond stress between concrete and plain reinforcing bars may be assumed at 4% of the compressive strength, or 2% in the case of drawn wire. In the best types of deformed bar, the bond stress may be increased, but not to exceed 5% of the compressive strength of the concrete.

7. REINFORCEMENT.

The tensile or compressive stress in steel should not exceed 16 000 lb. per sq. in.

In structural steel members, the working stresses adopted by the American Railway Engineering Association are recommended.

8. MODULUS OF ELASTICITY.

The value of the modulus of elasticity of concrete has a wide range, depending on the materials used, the age, the range of stresses between which it is considered, as well as other conditions. It is recommended that, in computations for the position of the neutral

axis, and for the resisting moment of beams, and for compression of concrete in columns, it be assumed as:

(*a*) One-fortieth that of steel, when the strength of the concrete is taken as not more than 800 lb. per sq. in.

(*b*) One-fifteenth that of steel, when the strength of the concrete is taken as greater than 800 lb. per sq. in. and less than 2 200 lb. per sq. in.

(*c*) One-twelfth that of steel, when the strength of the concrete is taken as greater than 2 200 lb. per sq. in. and less than 2 900 lb. per sq. in., and

(*d*) One-tenth that of steel, when the strength of the concrete is taken as greater than 2 900 lb. per sq. in.

Although not rigorously accurate, these assumptions will give safe results. For the deflection of beams which are free to move longitudinally at the supports, in using formulas for deflection which do not take into account the tensile strength developed in the concrete, a modulus of one-eighth of that of steel is recommended.

CHAPTER IX.

Conclusion.

In the preparation of this Final Report, 21 members have taken a more or less active part; all members have agreed to it in its present form.

The Joint Committee acknowledges its indebtedness to its subcommittee on design, Professors Talbot, Hatt, and Turneaure, for their invaluable and devoted service.

The Joint Committee believes that there is a great advantage in the co-operation of the representatives of different technical societies, and trusts that a similar combination of effort may be possible, some time in the future, to review the work done by the present Committee, and to embody the additional knowledge which will certainly be obtained from further experimentation and practical experience with this important material of construction.

Respectfully submitted,

* Mr. Godfrey dissents from the portion of the Report relating to stirrups and their treatment. He would give stirrups and short shear members no recognition, for the reason that he holds that they have not shown themselves to have any definite value in tests, and that analysis fails to show that any definite value can be ascribed to them; he also believes that dependence on stirrups to take end shear has resulted in much unsafe construction and some failures. He would take care of diagonal tension by bending up some of the main reinforcing rods and anchoring them for their full tensile strength beyond the edge of support. He recommends that bends be made close to the supports for the upper bends and at quarter points for the lower bends in beams carrying uniform load. For girders carrying beams bends should be made under the beams. For anchorage he recommends that the rod should extend 40 to 50 diameters beyond the point where it intersects a line drawn, at 45° with the horizontal, from the bottom of the beam at the face of the support.

He recommends that the stress in bent-up rods be assumed to be that obtained by multiplying the excess of shear over that taken by the concrete (at 40 or 50 lb. per sq. in.) by the secant of the inclination of the rod with the vertical.

Mr. Godfrey also dissents from all parts of the Report relating to rodded columns, or columns having longitudinal rods without close-spaced hooping, for the reason that he holds that such reinforcement has not shown itself to have any definite value in tests on columns, and that analysis fails to show that any definite value can be ascribed to it, when such analysis takes into account the necessity for toughness in all columns; he also believes that dependence on such reinforcement has led to much unsafe construction and many failures. He would recognize as reinforced concrete columns only such columns as have in addition to the longitudinal rods a complete system of close-spaced hooping. He objects to the reading of Chapter VII, Section 9, Paragraph (*b*) as being capable of interpretation that hooped columns are given an advantage in the matter of unit stresses only below ten diameters in height. He recommends the standardization of hooped columns, and suggests that columns be reinforced by a coil or hoops of round steel having a diameter one-fortieth of that of the external diameter of the column and eight upright rods wired to the same, the pitch of the coil being one-eighth of the column diameter. He would consider available for resisting compressive stress, the entire area of the concrete of a circular column or of an octagonal column, but no part of the longitudinal rods or hooping. In a square column only 83% of the area of concrete would be considered available. The compression he would recommend on columns (for 2 000-lb. concrete) would be:

$$P = 670 - 12\,\frac{l}{d}$$

where P = allowable compression, in pounds per square inch;
l = length of column, in inches;
d = diameter of column, in inches.

CHAPTER X.

APPENDIX.

SUGGESTED FORMULAS FOR REINFORCED CONCRETE CONSTRUCTION.

These formulas are based on the assumptions and principles given in the chapter on design.

1. STANDARD NOTATION.

(a) Rectangular Beams.

The following notation is recommended:

f_s = tensile unit stress in steel;
f_c = compressive unit stress in concrete;
E_s = modulus of elasticity of steel;
E_c = modulus of elasticity of concrete;
$n = \frac{E_s}{E_c}$;
M = moment of resistance, or bending moment in general;
A_s = steel area;
b = breadth of beam;
d = depth of beam to center of steel;
k = ratio of depth of neutral axis to depth, d;
z = depth below top to resultant of the compressive stresses;
j = ratio of lever arm of resisting couple to depth, d;
$jd = d - z$ = arm of resisting couple;
p = steel ratio $= \frac{A}{bd}$.

(b) T-Beams.

b = width of flange;
b' = width of stem;
t = thickness of flange.

(c) Beams Reinforced for Compression.

A' = area of compressive steel;
p' = steel ratio for compressive steel;
f_s' = compressive unit stress in steel;
C = total compressive stress in concrete;
C' = total compressive stress in steel;
d' = depth of center of compressive steel;
z = depth to resultant of C and C'.

(*d*) *Shear, Bond and Web Reinforcement.*

V = total shear;
V' = total shear producing stress in reinforcement;
v = shearing unit stress;
u = bond stress per unit area of bar;
o = circumference or perimeter of bar;
Σo = sum of the perimeters of all bars;
T = total stress in single reinforcing member;
s = horizontal spacing of reinforcing members.

(*e*) *Columns.*

A = total net area;
A_s = area of longitudinal steel;
A_c = area of concrete;
P = total safe load.

2. Formulas.

(*a*) *Rectangular Beams.*

Position of neutral axis,

$$k = \sqrt{2pn + (pn)^2} - pn \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Arm of resisting couple,

$$j = 1 - \frac{1}{3}k \quad \ldots\ldots (2)$$

[For $f_s = 15\,000$ to $16\,000$ and $f_c =$ 600 to 650, j may be taken at $\frac{7}{8}$.]

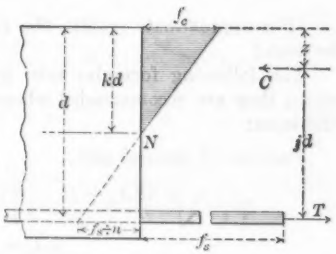

Fig. 3.

Fiber stresses,

$$f_s = \frac{M}{A_s jd} = \frac{M}{pjbd^2} \quad \ldots\ldots\ldots (3)$$

$$f_c = \frac{2M}{jkbd^2} = \frac{2pf_s}{k} \quad \ldots\ldots\ldots (4)$$

Steel ratio, for balanced reinforcement,

$$p = \frac{1}{2} \frac{1}{\frac{f_s}{f_c}\left(\frac{f_s}{nf_c} + 1\right)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

(*b*) T-*Beams.*

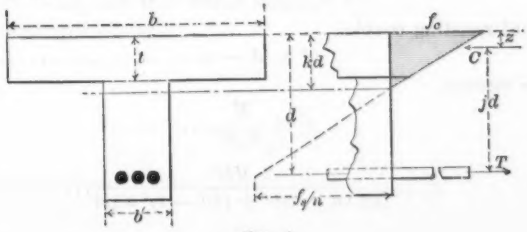

Fig. 4.

Case I. When the neutral axis lies in the flange, use the formulas for rectangular beams.

Case II. When the neutral axis lies in the stem.

The following formulas neglect the compression in the stem.

Position of neutral axis,

$$kd = \frac{2\,ndA_s + bt^2}{2\,nA_s + 2\,bt} \quad \ldots\ldots(6)$$

Position of resultant compression,

$$z = \frac{3\,kd - 2\,t}{2\,kd - t} \cdot \frac{t}{3} \quad \ldots\ldots(7)$$

Arm of resisting couple,

$$jd = d - z \quad \ldots\ldots(8)$$

Fiber stresses,

$$f_s = \frac{M}{A_s jd} \quad \ldots\ldots(9)$$

$$f_c = \frac{Mkd}{bt(kd - \frac{1}{2}\,t)jd} = \frac{f_s}{n} \cdot \frac{k}{1-k} \quad \ldots\ldots(10)$$

(For approximate results, the formulas for rectangular beams may be used.)

The following formulas take into account the compression in the stem; they are recommended where the flange is small compared with the stem:

Position of neutral axis,

$$kd = \sqrt{\frac{2\,ndA_s + (b - b')\,t^2}{b'} + \left(\frac{nA_s + (b - b')\,t}{b'}\right)^2} - \frac{nA_s + (b - b')\,t}{b'} \quad \ldots\ldots(11)$$

Position of resultant compression,

$$z = \frac{(kdt^2 - \frac{2}{3}\,t^3)b + [(kd - t)^2\,(t + \frac{1}{3}\,(kd - t))]b'}{t(2\,kd - t)b + (kd - t)^2\,b'} \quad \ldots\ldots(12)$$

Arm of resisting couple,

$$jd = d - z \quad \ldots\ldots(13)$$

Fiber stresses,

$$f_s = \frac{M}{A_s jd} \quad \ldots\ldots(14)$$

$$f_c = \frac{2\,Mkd}{[(2\,kd - t)bt + (kd - t)^2\,b']jd} \quad \ldots\ldots(15)$$

(c) Beams Reinforced for Compression.

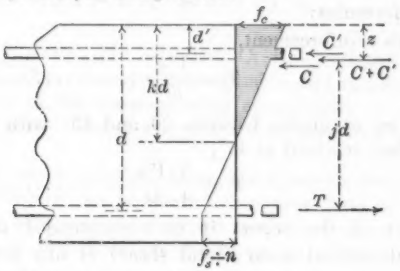

FIG. 5.

Position of neutral axis,

$$k = \sqrt{2\,n\left(p + p'\,\frac{d'}{d}\right) + n^2(p + p')^2} - n(p + p') \ldots\ldots (16)$$

Position of resultant compression,

$$z = \frac{\frac{1}{3}\,k^3 d + 2\,p'nd'\left(k - \frac{d'}{d}\right)}{k^2 + 2\,p'n\left(k - \frac{d'}{d}\right)} \ldots\ldots (17)$$

Arm of resisting couple,

$$jd = d - z \ldots\ldots (18)$$

Fiber stresses,

$$f_c = \frac{6M}{bd^2\left[3\,k - k^2 + \frac{6p'n}{k}\left(k - \frac{d'}{d}\right)\left(1 - \frac{d'}{d}\right)\right]} \ldots\ldots (19)$$

$$f_s = \frac{M}{pjbd^2} = n\,f_c\,\frac{1-k}{k} \ldots\ldots (20)$$

$$f_s' = n\,f_c\,\frac{k - \frac{d'}{d}}{k} \ldots\ldots (21)$$

(d) Shear, Bond, and Web Reinforcement.

For rectangular beams,

$$v = \frac{V}{bjd} \ldots\ldots (22)$$

$$u = \frac{V}{jd\,.\,\Sigma o} \ldots\ldots (23)$$

[For approximate results j may be taken at $\frac{7}{8}$.]

The stresses in web reinforcement may be estimated by means of the following formulas:

Vertical web reinforcement,

$$T = \frac{V's}{jd} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

Bars bent up at angles between 20 and 45° with the horizontal and web members inclined at 45°,

$$T = \frac{3}{4}\frac{V's}{jd} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

In the text of the report it is recommended that two-thirds of the external vertical shear (total shear) at any section be taken as the amount of total shear producing stress in the web reinforcement. V' therefore equals two-thirds of V.

The same formulas apply to beams reinforced for compression as regards shear and bond stress for tensile steel.

For T-Beams,

$$v = \frac{V}{b'jd} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

$$u = \frac{V}{jd \,.\, \Sigma o} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

[For approximate results j may be taken at $\frac{7}{8}$.]

(*e*) *Columns.*

Total safe load,

$$P = f_c\,(A_c + nA_s) = f_cA(1 + (n-1)p) \ldots\ldots\ldots (28)$$

Unit stresses,

$$f_c = \frac{P}{A(1 + (n-1)p)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (29)$$

$$f_s = n\,f_c \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

DISCUSSION

A. H. RHETT,* ASSOC. M. AM. SOC. C. E. (by letter).—*Integral Water-Proofing of Concrete.*—In this valuable and interesting report the elusory subject of the water-proofing of concrete, or rendering it impervious to the percolation of water, again appears, and again invites discussion. Mr. Rhett.

Reduced to its most practical form, the question becomes merely whether or not concrete can be made non-porous; and, if so, what is the simplest, most effective, and cheapest method of doing it.

The first step in this direction should be, and is, the proper proportioning of the ingredients to fit so closely and compactly that no voids remain, and much experimenting and investigation has been done along these lines. Repeated experimenting, however, has seemed to show that, with the best possible grading, tamping, and mixing with available aggregates, there still remains from 10 to 15% of voids, and there is also an added percentage due to pocketing of water or air during the mixing and placing process.

It is not essential, of course, to close every void to render the concrete water-proof, as far as percolation through it is concerned, because continuity of the voids will play a considerable part in any percolation; but the rendering of the concrete absolutely non-porous is desirable sometimes for other reasons. The entrance into the pores of water affected with acid or alkaline properties gives rise to disintegration of the concrete, from the reaction of the acid or alkali and the free lime always present, and the preservation of the integrity of the concrete is more important than the actual water-proofing of it. Furthermore, any such reaction would eventually render the concrete pervious, even if it were not so originally.

The problem then, in its final form, becomes one of closing this 10 to 15% of voids that remain after the best proportioning has been obtained and those that occur from the pocketing of water or air in the concrete during the mixing process, or from friction between the particles of the aggregates in placing; and a corrective must be sought in means other than proportioning.

A study of the hydration of Portland cement seems to show that such a correction lies latent in the cement itself, and can be made available under proper treatment.

It has been shown† that the so-called beta-orthosilicate element of Portland cement is very slow to hydrate, and that but little trace of its hydration is found in any cement before 7 days, and in some cases it does not appear until 28 days, but that when this hydration does commence it progresses as long as water is present, and with a great

* New York City.

† *Technologic Paper No. 43*, U. S. Bureau of Standards.

Mr. Rhett.

increase in volume. This increase in the volume of Portland cement when continually mixed with water has been also strikingly shown by Nathan C. Johnson,* Assoc. M. Am. Soc. C. E.

This action of the cement, of course, must occur in concrete where the mixing is thorough and when water is held in the mix long enough to permit it. A further point to note is that chemical action of this sort is retarded by pressure, and would be most active in the direction of least resistance and consequently into the void spaces. It is also an interesting fact that this beta-orthosilicate element hydrates with an amorphous and not a crystalline structure. If the latter were the case, there would be a tendency to disrupt the concrete, but the amorphous texture of the increased volume enables it to adjust itself to the void forms and fill them.

It is a well-known fact in daily practice, and has recently been again noted,† that, with a given mix, the strength, and therefore density, will vary directly with the length of time required to dry out.

It would seem entirely possible, therefore, theoretically to get a non-porous concrete:

(1)—If the aggregates were properly proportioned;
(2)—If the mixing were thorough;
(3)—If the placing and tamping were properly done;
(4)—If the quantity of water used were correct; and
(5)—If the forms were kept on long enough to insure the retention of sufficient water to hydrate the cement thoroughly.

Any practical man knows the difficulty and expense, if not the impossibility, of obtaining these conditions, and it becomes a very practical question as to whether or not they might not be obtained by a less expensive and more automatic or fool-proof method.

Answer to this question has been sought in the so-called integral water-proofing compounds, and they have been produced on several theories.

The simplest was the addition of some very finely particled inert material that would fill the voids. There seems to be no reason to doubt that the addition of such material might, to a certain degree, compensate for a faulty proportion of aggregates, but could scarcely be relied on to fill such voids as are caused by the mechanical pocketing of air and water in the concrete during mixing, or by the friction of the particles in placing.

Another theory has been to mix with the concrete a water-repellent material that will coat the voids and pores and prevent absorption.

* "Materials vs. Methods—Testimony of Moving Pictures in the Study of Concrete," *Engineering Record*, December 4th, 1915.

† "The Strength and Other Properties of Concrete as Affected by Materials and Methods of Preparation," *Technologic Paper No. 58*, U. S. Bureau of Standards.

Mr. Rhett.

It is difficult to see, though, how such a material could coat the pores without coating also the particles of cement and preventing proper hydration, or how it could be relied on to coat every pore.

A better and more rational theory, however, has been to add a material which will lubricate the aggregates, and thus enable them to settle in a denser mass by eliminating the friction, and which will also act as an inert void filler. Such a material would eliminate the necessity for much tamping, and would compensate to a certain degree for a faulty proportion of aggregates; but there would probably still remain a certain percentage of voids due to the air and water pockets formed in the mixing. These, it would seem, can really only be eliminated by the swelling action caused by the full hydration of the cement, as described previously.

If, however, a material could be added to the concrete that would not only act as a lubricator and void filler, but, in addition, would tend to hold the water in the concrete and prevent too quick drying, it would certainly seem—on perfectly rational grounds—to compensate to a considerable degree for faulty proportioning, careless placing and tamping, inadequate mixing, and early removal of forms.

Such action, moreover, would be automatic, and might well prove much less expensive and more practical than the conditions necessary to obtain the same result without the addition of the compound.

The object of this discussion has been to show, if possible, that there is a theory which is rational and will explain the success that has attended the use of some of these compounds, in so many instances, and that the practical evidence of their effectiveness cannot be candidly disregarded.

To obtain this success, these materials should be used intelligently. There is nothing miraculous about their action. They cannot compensate for cracking or breaking of the concrete, for very lean mixes, or for an acid or alkaline content in the sand, but they can and do compensate, to a degree which is eminently practical, for faulty proportioning, careless placing and tamping, improper mixing, and too quick removal of the forms.

The Appendix to the report repeats the usual or standard textbook formulas for proportioning concrete beams. It has always seemed to the writer that though these formulas are normal for the analysis of a beam already built, they certainly operate in a reverse and roundabout manner for proportioning a new beam.

One must first find p, a proportion of an unknown area, then K, a proportion of an unknown depth, then j, which is a fraction of the real depth, and then d; and, from d, one then works back to the absolute value of p.

It is perfectly possible to solve a reinforced concrete beam as directly as a steel beam, and from the same basic elements, that is, the

Mr. Rhett.

bending moment and the assumed fiber stresses and moduli of elasticity. The writer has used such formulas for years. The formulas given in the report are derived fundamentally from the summation of the horizontal stresses in the concrete and steel; those used by the writer are derived from the moments of these forces. For instance, taking the first condition, a beam reinforced on the tension side only, and using the notation adopted, except that absolute values will be considered instead of proportional ones; that is, Kd will be represented as y, and pbd as a, and, referring to Fig. 6, we would have:

$$\Sigma \text{ of moments of horizontal stresses} = \frac{1}{3} f_c y^2 + a f_s y_2 = 0$$

$$\Sigma \text{ of horizontal stresses} = \frac{1}{2} y f_c - a f_s = 0$$

and

$$y_2 = \frac{f_s}{n f_c} y,$$

from which would result, if $\frac{f_s}{f_c}$ is expressed as r, and M is the moment per unit of width of beam, say, inch-pounds per inch of width,

$$y = \sqrt{\frac{M}{f_c \left(\frac{1}{3} + \frac{1}{2}\frac{r}{n}\right)}}; \; d = y\left(1 + \frac{r}{n}\right); \; a = \frac{y}{2r};$$

for a set of specified values such as $n = 15$, $f_s = 20\,000$ lb., $f_c = 600$ lb., $r = 33.3$,

$$y = \sqrt{\frac{M}{864}}, \; d = 3.2\, y, \text{ and } a = \frac{y}{67}.$$

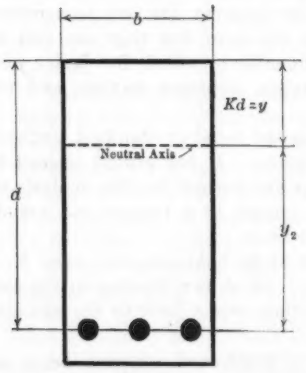

FIG. 6.

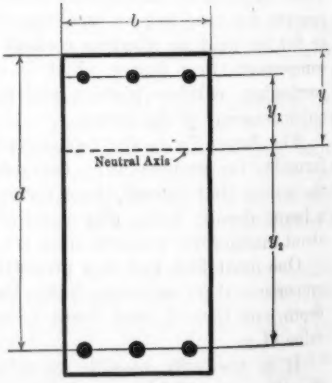

FIG. 7.

Mr. Rhett.

For beams reinforced on both sides, the formulas are not so easily derived, but become equally simple of application for specified values. Two assumptions would have to be made, however: first, the usual one of the ratio of y_1 to y (referring to Fig. 7); and, second, the relative area of a', the area of the steel in compression, to a. The latter assumption would be dictated largely by practical conditions, as in a series of spans of restrained beams. Let $a' = Ca$.

Then,

$$\Sigma M = \frac{1}{3} y^2 f_c + C a f_s' y_1 + y_2 a f_s$$

$$\Sigma H = a f_s - C a f_s' - \frac{1}{2} y$$

which give,

$$M = f_c y^2 \left[\frac{1}{3} + \frac{r}{2n}\left(1 + \frac{C n y_1}{r y}\right)\right]$$

$$y = \sqrt{\frac{M}{f_c\left[\frac{1}{3} + \frac{r}{2n} + \frac{C}{2}\frac{y_1}{y}\right]}}$$

$$d = y\left(1 + \frac{r}{n}\right)$$

$$a = \frac{y}{2r}\left(1 - \frac{C n y_1}{r y}\right)$$

$$a' = C a,$$

which equations become identical with those for single reinforcement when $C = 0$. With specified values, these become equally simple. Using the same notation and with $C = 0.5$ and $\frac{y_1}{y} = 0.75$:

$$y = \sqrt{\frac{M}{973}}$$

$$d = 3.22\, y$$

$$a = \frac{y}{55}$$

$$a' = \frac{y}{27.5}$$

For T-beams reinforced for tension in stem only, and the neutral axis lying within the flange, the forms are the same as for rectangular beams reinforced on one side only, except that M and a represent values per unit width of flange and not of stem.

In the case of the T-beam the axis of which lies in the stem, very simple formulas can be similarly derived with two assumptions which are entirely within the realm of rationality, considering the very radical assumption in T-beam design in regard to the effective width of the flange. These assumptions are, referring to Fig. 8, that the

Mr. Rhett.

averages, $f_c = \frac{1}{2} f_c$ and $Z = \frac{1}{3} t$, are both on the side of safety. Expressing t as Ky, then,

$$\Sigma M = \frac{1}{2} K f_c y \left(y - \frac{1}{3} K y \right) + a f_c y_2$$

$$\Sigma H = \frac{1}{2} K y f_c - a f_s$$

and

$$y = \sqrt{\frac{M}{\frac{1}{2} K f_c \left(1 - \frac{1}{3} K + \frac{r}{n} \right)}}$$

$$d = y \left(1 + \frac{r}{n} \right)$$

$$a = \frac{y}{2 r}$$

$$t = K y$$

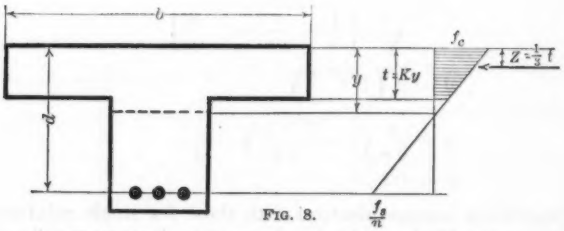

FIG. 8.

TABLE 1.—VALUES OF a FOR ROUND BARS.

DIAMETER, IN INCHES.		⅜	7/16	½	9/16	⅝	11/16	¾	13/16	⅞
Area, a, in square inches.		0.11	0.15	0.196	0.248	0.307	0.371	0.442	0.518	0.601
Values of a spacing.	3 in.	0.037	0.050	0.065	0.082	0.102	0.124	0.147	0.173	0.200
	3½ in.	0.032	0.043	0.056	0.071	0.088	0.106	0.125	0.148	0.172
	4 in.	0.027	0.037	0.049	0.062	0.077	0.093	0.110	0.130	0.150

With the same specified unit values as before, and with $K = 0.75$, the formulas reduce to the same simple forms:

$$y = \sqrt{\frac{M}{675}}$$

$$d = 3.22\, y$$

$$a = \frac{y}{67}$$

$$t = 0.75\, y$$

All these formulas can be read directly from a slide-rule, and the actual area and spacing of the bars could be taken from a table such as Table 1, in which the moment is expressed in inch-pounds per inch of width of beam. Mr. Rhett.

WILLIAM FRY SCOTT,* ASSOC. M. AM. SOC. C. E. (by letter).—There are many reasons why this Society, as a body, should not approve the Final Report of this Committee as representing an expression of "the present state of the art." One reason will be sufficient to prove this statement, and may be understood by a study of the diagram, Fig. 9. Mr. Scott.

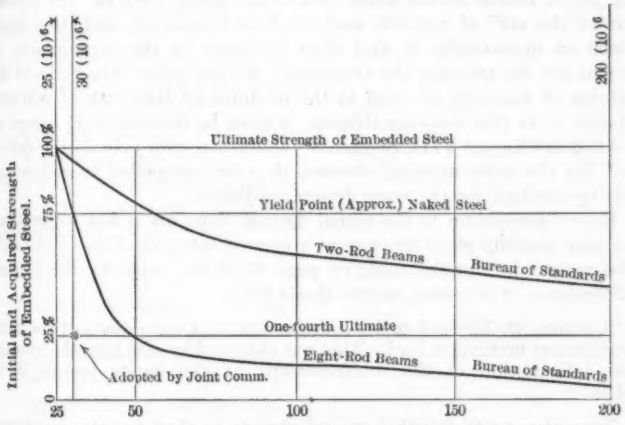

FIG. 9.

This diagram gives the variations in the modulus of elasticity (so-called for want of a better term) of embedded steel, in two of the several groups of reinforced concrete beams made and tested under the direction of Mr. Humphrey, the Secretary of the Committee, and, as computed by the writer on the basis of Assumption *c* 4, page 1125, of the report. On the other hand, the modulus of elasticity of naked steel is assumed, by the Committee, to be identical with that for embedded steel; as is also the case, by the writers of the paper† reporting the beam tests referred to.

This paper has a dual character: On the one hand, it contains the most valuable report of, probably, the most comprehensive series of tests of concrete and reinforced concrete to date. The data are pre-

* Dunville, Ont., Canada.

Mr. Scott.

sented in such a thorough manner that they will serve for analysis by a stranger to the experiments just as well as they did for those who planned them. On the other hand, it contains an elaborate thesis that is in no way supported by the data in Tables 3, 33, 34, 35, and 36, and Appendices I and II, of the paper. This thesis follows more or less closely the "design" assumptions on page 1125 of the report of the Committee, and the authors seem to have lost sight of the fact that their real object was to investigate the correctness or falsity of those very assumptions. This thesis shows a tendency to neglect to deal with a long list of partial truths which lead to the whole truth in "the present state of the art" of concrete and reinforced concrete, and its authors missed an opportunity to find clear evidence, in the experiments, to account for the anomaly the Committee devised when "the ratio of the modulus of elasticity of steel to the modulus of elasticity of concrete is taken at 15 [for working stresses, it must be remembered] except as modified in Chapter VIII, Section 8"; and when, "for calculating deflection" for the same working stresses, they are compelled to reduce the ratio by one-half for the same design conditions.

Before proceeding to the actual figures, there are a few suggestions that may possibly clear the way to a correct interpretation of the data to be reviewed. For instance; on page 43 of the paper by the Bureau of Standards, it is stated, on the thesis side:

"Column 12, Tables 6 to 21, contains the unit elongation of the reinforcement at maximum load. This was obtained by dividing the average total deformation of the reinforcement by the gauge length, 29.25 inches."

Now, the gauge length here referred to is that for the reinforced concrete beam under analysis. Then, again, on page 45 of the same paper, there is the statement:

"Given the unit elongation of the reinforcement and assuming a coefficient of elasticity of 30 000 000 the unit stress is easily obtained."

Again, it should be noted that the unit elongation here referred to is that given by the deformations in the plane of the steel in the beam to be analyzed, but the assumed coefficient of 30 000 000 can be none other than that for naked steel.

Immediately following the foregoing quotation the paper states:

"It must be borne in mind, however, that the proportionality of stress and strain holds only within the elastic limit of the material."

Now, a close analysis of the following single example, given by the writer, shows clearly that the modulus of elasticity (so-called) of embedded steel has no relation to that for naked steel, and it also shows that the elastic limit of naked steel bears no relation to that for embedded steel.

Herewith is the example, taken from the paper: Mr. Scott.

It deals with the gravel concrete beams Nos. 342, 343, and 344, one year old. Twenty-one collateral specimens of the concrete used in these beams were tested in cylinders, 8 in. in diameter and 16 in. long, and developed an average unit load of 5 245 lb. per sq. in. at failure—maximum plus 10% and minimum minus 14½ per cent. The same specimens developed an average modulus of elasticity of 5.395 $(10)^6$ lb. per sq. in. with a maximum of 5.86 $(10)^6$ and a minimum value of 48 $(10)^6$ lb. per sq. in.

Now, as to the three beams:	Beam No. 342.	Beam No. 343.	Beam No. 344.
Loads given in paper in "analysis of beam at Unit Elongation in Reinforcement Less than that at Yield Point".....	6 000	5 500	6 500
Bending moments, in inch-pounds divided by (bd^2)...	204.5	189.5	219.6
Deformations, upper fiber, in millionths of an inch per inch.	325	282	420
Deformations, steel fiber, in millionths of an inch per inch	872	603	1 111
Neutral axis, distances from top fiber	0.271d	0.319d	0.275d
Now take these data and assume, tentatively, that there is straight-line deformation. Then the stresses on the extreme upper fiber of the concrete, in pounds per square inch, would be.....	1 640	1 320	1 740
and the moduli of elasticity, on the basis of these stresses and the foregoing deformations, would be.....	5.05$(10)^6$	4.68$(10)^6$	4.15$(10)^6$

Thus, since the initial modulus of elasticity found for this same concrete ranged from 5.86 $(10)^6$ to 4.8 $(10)^6$ in standard cylindrical specimens, it must be apparent that straight-line stress was practically obtained on these three beams. In fact, comparing Beam No. 342 with its particular collateral specimen, the beam developed 5.05 $(10)^6$ for a stress of 1 640 lb. per sq. in., or 31½% (ultimate) for cylinders, and the cylinder 5.22 $(10)^6$ at initial stress.

Now, this being the status, for the concrete in compression, it is at once apparent that in the three beams there were stresses of 46 000, 43 300, and 49 500 lb. per sq. in. in the reinforcement, if Assumption $c4$ of the report is correct; and then the modulus of elasticity of the

Mr. Scott.

embedded steel should equal this unit stress divided by the unit deformation recorded in the "log" for the particular condition of loading under consideration, and would be.... and not 30 (10)^6, as laid down by the Committee.

Then, again (and this is particularly interesting), the breaking loads on these beams, in pounds, would be.

and these exceed that at less than yield point (so-called in the paper) by.....

	Beam No. 342.	Beam No. 343.	Beam No. 344.
	52.6(10)^6	71.2(10)^6	44.5(10)^6
	6 280	5 800	6 800
	5% only	6% only	5% only

In other words, it is found that the modulus of elasticity of the embedded steel in these beams ranges from 71 (10)^6 to 44½ (10)^6 when they are within 6% of their ultimate strength.

Then, again, take the average reading for the three beams at the following applied loads (in pounds).....	2 000	4 000	5 500
Deformations, upper fiber, in millionths of an inch per inch.....	76	146	293
Deformations, steel fiber, in millionths of an inch per inch.....	67	154	650
Neutral axis, distances from top fiber.....	0.53d	0.485d	0.310d
Bending moments, in inch-pounds divided by bd^2.....	84.4	144.4	189.4
From which the stresses on the upper fiber, in pounds per square inch, are.....	387	710	1 360
and these are the following percentages of the average ultimate unit load per square inch on the twenty-one collateral specimens.....	7.4%	13.6%	26%
for which the moduli of elasticity are.....	5.1(10)^6	4.85(10)^6	4.65(10)^6
On the basis of Assumption $c4$ of the report, the stresses on the steel, in pounds per square inch, are.....	20 700	35 200	43 000

Mr. Scott.

	Beam No. 342.	Beam No. 343.	Beam No. 344.
and these stresses divided by the unit deformation (modulus of elasticity) are.....	$310(10)^6$	$230(10)^6$	$66(10)^6$
and, as 6 290 lb. is the mean maximum applied load for the three beams, it is found that for loads at the following percentages of maximum.....	32%	64%	87%
the moduli of elasticity of embedded steel are.....	10 times	7 times	2 times

that laid down by the Committee.

The concrete of these beams was very rich in cement, but exactly similar results can be shown with concrete beams which are poor in cement.

The writer has developed his own figures from the data in the "Log" of the paper mentioned, and they produce entirely different results from those given in the "Summary of Tests", both in the Bureau of Standards paper.

The two curves on Fig. 9 are based on a general analysis of two groups only, namely two-rod beams and eight-rod beams.

Mr. Gayler.

CARL GAYLER,* M. AM. SOC. C. E. (by letter).—The writer gladly acknowledges the great merits of the work of the Committee, and has no doubt that the report will be for a long time an aid to the concrete engineer as a book of reference, guiding him in his work and correcting or sustaining him in his judgment. Aside from a few objections which can be raised, it will probably be accepted as a standard by the Profession. Still, in the writer's opinion, there are such objections, and he begs to state them.

It is to be regretted that so little prominence is given to the important problem of eliminating the dangers from laitance. Every engineer, active in reinforced concrete work, has been aware of this danger for years; many engineers (among them the writer) have come to its realization only after bitter experience; but few have had a clear conception of the magnitude of the problem before reading the classic paper "Water the Chief Factor in the Making of Good Concrete", by Nathan C. Johnson, Assoc. M. Am. Soc. C. E.†

Now, in the Report, Chapter II, Section 2, laitance is not mentioned as one of the causes through which reinforced concrete structures fail, nor is there—and this is more important—any cautioning

* St. Louis, Mo.

† *The Engineering Record*, December 30th, 1916.

Mr. Gayler.

of the inspectors on this point in Section 3 of the same chapter. The "Destructive Agencies" mentioned are: "Corrosion of Metal Reinforcement", "Electrolysis", "Sea Water", "Acids", "Oils", and "Alkalies", but not one word of "Laitance."

The short references in Chapter IV, Section 3, to the removal of laitance can hardly be considered as emphasizing the subject sufficiently, nor is mention made of the chief agency of the trouble, that is, excess of water.

The field covered by reinforced concrete work has grown to such astonishing dimensions that an engineer, no matter what his specialty, to be competent, must have a general knowledge of the principles and requirements of such work. Whether he is engaged in hydraulic works, power stations, bridge or irrigation work, it confronts him in the shape of foundations, conduits, reservoirs, retaining walls, or viaducts. Now, of this immense field, many features of which are still in the midst of evolution, and for which the practising engineer expected enlightenment from the report, not so much on detailed features as through broad, general rules, very little is to be found, with the exception of the indoor slab.

It will be objected that the different types of structures just mentioned do not come within the scope of a report on concrete and reinforced concrete (and, in fact, the Committee makes this claim in the introduction to the report), that such a report is complete after full presentation of the qualities of the materials and of the principles underlying their wise and economical use. Even granting the force of this objection, it is thought that by allowing one-tenth of the space allotted to the flat slab, with its dropped panel, column capital, wall girders, etc., to a few other types of structures of general interest, the value of the report would have been much increased. Some expression of opinion, for instance, on the problems of skeleton retaining walls, on the advantages of the hinged arch, slabs of bridge floors (very different, indeed, with their delicate problems of drainage and shrinkage, from the indoor slab), etc., in the form of concise résumés of the experience of the eminent engineers to whom we owe this report, would have been of great value to the Profession.

Reinforced concrete structures are, essentially, heavy structures. Their success and appearance depend on unyielding support during construction. In many important cases the designing of falsework and centers requires as careful study as the planning of the superstructure; and their maintenance, until the full completion of the work, as much attention as the depositing of the concrete. A reference in the report to this subject, perhaps with the addition of permissible stresses in the materials used, might have been expected. The case is entirely different from the additional types referred to previously. Falsework and centers may be said to form, during construction, an integral part

of the superstructure, and it seems that a general report on concrete and reinforced concrete is not complete if this subject is omitted. Mr. Gayler.

There is one other point on which the writer takes exception to the report, that is, the exclusion of high-grade steel. The Committee has been careful in the wording: it merely recommends the structural grade, but the unit stresses, adopted in the report, practically eliminate the use of high-carbon steel.

High-carbon steel is in general use for reinforced concrete work. It is specified, on even terms, with structural steel, in the standard specifications of the American Society for Testing Materials, of the American Railway Engineering Association, in the building codes of our larger cities, and in the specifications for highway bridge work; and railroad and municipal engineers, as well as engineers in private practice, use it.

As no explanation is given in the report, of the Committee's preference for the milder grade, it may be assumed that the question of greater brittleness of the harder steel has been the deciding one. On this point it is found that Taylor and Thompson, in their treatise on "Concrete, Plain and Reinforced", in a lengthy and clear discussion (p. 414) on the advisability of using hard steel, in which due stress is laid on the difference in the use of steel for bridge work and for reinforced concrete work, and in which careful inspection at the mills is insisted on as an efficient means of obviating dangers from brittleness, end the paragraph with the following (as it seems to the writer) unanswerable argument:

"Steel which can be employed with safety for all locomotive and car wheels of the country certainly cannot be discarded as unsafe for concrete, provided similar precautions are taken in its purchase."

From his own experience, the writer considers high-carbon steel for reinforced concrete work a thoroughly safe material. With proper care and judgment used, where any bending is to be done, no undue risks are run.

Assuming now the safe use of hard steel to be granted (its general use cannot be denied), we reach the important question whether steel with a higher percentage of carbon should be proportioned for the same low unit stress as milder steel (always assuming that the conditions imposed by the bond stress are fulfilled). As far as general practice goes, the answer has been, almost universally, in the negative.

The difference in the unit stresses allowed for high steel over structural steel may be stated, approximately, to be as follows: In railroad work from 2 000 to 3 000 lb.; highway bridge work from 2 000 to 4 000 lb.; and city building laws from 4 000 to 6 000 lb. (the building laws of the City of St. Louis, for instance, specify 14 000 lb. for medium steel and 20 000 lb. for high elastic limit steel).

Mr. Gayler.

Considering that, in the report, not less than fifteen different unit stresses are specified for stone or gravel concretes, according to the nature of the aggregates and the ratio of the mixtures, it seems strange to find the single line "the tensile or compressive stress in steel should not exceed 16 000 lb. per sq. in.", covering the whole subject of proportioning steel, whether the elastic limit is 30 000, 40 000, or 50 000 lb., or the ultimate strength 50 000, 70 000, or 80 000 lb. per sq. in.

Taking into consideration that this question of permissible unit stresses in the steel affects the universal practice in concrete work all over the country, and for every class of such work, there must have been strong reasons for the action of the Committee, and engineers hope to find them stated in the concluding answer to the different discussions on the report.

Mr. Hinckley.

H. V. HINCKLEY,* M. AM. SOC. C. E. (by letter).—Three points pertaining to "coarse aggregate" occur to the writer as being possibly worthy of mention, namely, large aggregate, glassy aggregate, and strong aggregate.

That "a large aggregate produces a stronger concrete than a fine one" will not be questioned by any competent engineer. It is fortunate, however, that the point has been brought out, because public officials are apt to look on coarse aggregate as a shirking of duty on the part of the rock crusher rather than the exercise of good judgment by the engineer.

The following substitute clause is offered as a suggestion: "The Committee does not feel warranted in recommending the use of blast-furnace slag," flint, or other aggregates which produce smooth, glassy faces, especially for reinforced concrete in which high strains are to be developed.

It is fully as important that the coarse aggregate shall be of tough, strong rock, as it is that "fine aggregate should always be tested for strength." Of two classes of rock (other conditions being equal), the class that, as a beam, will support the heavier load will make, if crushed for coarse aggregate, the stronger concrete. When concrete fails under compression, it fails in tension, and, in failing, it generally splits through the coarse aggregate rather than around it, and as the rock thus broken makes up the greater portion of the section of failure, the strength of the concrete is largely dependent on the strength of the stone. The writer recently stated†:

"Every engineer of experience should know that, under any ordinary concrete specifications, he can build two slabs side by side, using the same sand, the same cement, the same proportion, the same time of mix in the same machine, and at the end of 90 days have one slab at least twice as strong as the other."

* Oklahoma, Okla.

† *Transactions*, Oklahoma Soc. of Engrs., Vol. III.

Mr. Hinckley.

If the writer had to build a reinforced concrete structure, in which high strains were to be developed, he would pay as much attention to the modulus of rupture of the rock to be used as he would to the tests of the fine aggregate. It is time for the Society to get away from the idea that any old stone will make good concrete. A "clean, hard, and durable" stone may be brittle and weak, and it might not be out of place to add, at least, the word "strong."

Since writing the foregoing, the writer's attention has been called to Professor George A. Hool's "Reinforced Concrete Construction", in which is found the only corroboration of the foregoing views which he has ever noticed. Professor Hool says: "Any stone is suitable which is clean and durable, and has sufficient strength to prevent the strength of the concrete from being limited by the strength of the stone," and this means that the stone must be as strong as the mortar.

Mr. Eddy.

HENRY T. EDDY,* ESQ. (by letter).—*1.—The Thickness of Flat Slabs.*—In the first place the writer desires to consider somewhat critically the formula recommended in the report for the value of the minimum total thickness, t, in inches, of a flat slab without dropped panels, in order to show that it is a formula not suited to give the minimum thickness, according to accepted principles in reinforced concrete design. The formula recommended in the report is:

$$t = 0.024\, l \sqrt{w} + 1.5 \qquad (1)$$

in which l = panel length or span between column centers, in feet, and $w = w_0 + w_1$, the sum of the live load, w_0, and the dead load, $w_1 = 12.5\, t$ lb. per sq. ft. Similar formulas have been proposed in the Chicago Ruling† and in the standard building regulations reported to the American Concrete Institute.‡

Equation (1) consists of two parts, the mean effective moment thickness, d, or the depth of the center of the steel below the compressed slab surface, and 1.5 in., which last includes half the thickness of the steel mat of crossed rods plus concrete fire-proofing at least 1 in. thick. Hence, we have the effective moment thickness

$$d = 0.024\, l \sqrt{w} \qquad (2)$$

an equation which, together with Equation (1), the writer has reason to believe is so far from being correct that it should not be recommended or regarded as expressing the minimum value, a conclusion that follows from considerations that will now be given in detail.

The general expression for the bending moment, due to the applied forces acting at any panel-wide vertical section of a square panel of

* Professor of Mathematics and Mechanics and Dean Emeritus, University of Minnesota, Minneapolis, Minn.

† *Engineering News*, September 24th, 1914.

‡ *Proceedings*, Am. Concrete Institute, Vol. XIII, 1917.

Mr. Eddy.

span l ft., when loaded with a total uniformly distributed load of w lb. per sq. ft., or a total load of $W = wl^2$ lb. per panel, may be written in the form:

$$12\ W\frac{l}{a} = 12\ w\frac{l^3}{a}\ \text{in-lb}.....(3)$$

in which a is a numerical divisor the value of which has frequently been recommended to be taken at about 24 or 25 for the section at mid-span and at -12 or -15 at the edge of the panel, with intermediate values, positive or negative, at sections situated between these. These, however, are the two sections which are most frequently taken into consideration.

Again, the general expression for the resisting moment of the steel that crosses any vertical cross-section of the panel which has an effective thickness of d in. and a total effective cross-section of steel of $A = 12\ pld$ sq. in., may be written in the form:

$$f_sAjd = 12f_spljd^2\ \text{in-lb}.....(4)$$

in which f_s, in pounds, is the unit stress in the steel, jd is the moment arm, $12l$ is the panel length, in inches, and p is the steel ratio of the section.

It is assumed ordinarily that when the direct tensile resistance of the concrete acting in parallel with the tensile resistance of the steel is neglected, the resisting moment must be equal to the applied moment. The writer, however, has reasons, which he has explained elsewhere, for believing that the applied moments are more than twice as large as the actual resisting moments shown by observation. In case this is the fact, it would only be necessary, in order to make Equations (3) and (4) equal, to assume, as the numerically correct value of a, a number which is the same multiple of the value of a, ordinarily assumed, that the applied moments are of the resisting moments. However, leaving this question unsettled for the present, and leaving also the value of a, which will be finally adopted as applicable at mid-span, undetermined, we may nevertheless equate the resisting moment to the applied moment, with the understanding that such a value of a will finally be adopted as may appear to be required by the facts. Hence

$$f_spjd^2 = w\frac{l^2}{a},$$

or,

$$d = \frac{l\,w}{\sqrt{f_sjpa}}.....(5)$$

Now compare Equation (5) for the effective thickness, d, with Equation (2), which was recommended in the report. In case Equation (2) is correct, it must be identical with Equation (5). To express

this relation more concretely, assume that $f_s = 16\,000$ lb. per sq. in., and that $j = 0.9$ at the mid-section. Then, in order that Equations (5) and (2) may be identical, we have Mr. Eddy.

$$16\,000 \times 0.9 \times (0.024)^2 pa = 1, \text{ or } pa = 0.12 \ldots\ldots\ldots (6)$$

Hence, when we take $a =$ 12, 15, 20, 24, 30, 40, 50, 60, we then have $p =$ 0.01, 0.008, 0.006, 0.005, 0.004, 0.003, 0.0024, 0.002, respectively.

It thus appears that in case Equation (2) is, in fact, a correct form of expression for d, then Equation (6) must also hold true; but as a in Equation (6) is a constant which is fixed by the position where the section is taken, at mid-span or elsewhere, and, moreover, is independent of both l and w, it follows from Equation (6) that p is also constant so long as a remains constant. If there is anything in the design of concrete beams, however, that has been indubitably established by experience, it is that the steel ratio increases with the relative thickness, that is, p increases with $\frac{d}{l}$, and the same principle applies to slabs also. Hence, Equations (1) and (2) are not, in fact, correct, and cannot be relied on to fix the minimum value of d, because they require a constant value of p, not in accordance with experience. In fact, p is found to be nearly twice as large in deep slabs for heavy loads as it is in shallow slabs for light loads, in case of well-designed slabs for any given span.

The reason for such increase in the value of p in case of deep beams is evident from the following considerations. In shallow beams and slabs the sharpness of the curvature is inversely proportional to d for a given limiting compression in the concrete at the top surface. The sharper the curvatures the greater the horizontal shearing distortions in the concrete at points distant from the sections where maximum moments occur. Concrete affords a resistance to shearing distortion which is small compared with its resistance to compression. In shallow beams high values of p are futile, for this reason, but, in deep beams, larger values of p may be used than in shallow beams, on account of their smaller shearing distortion. In slabs this still further reason may exist for an increase of p with $\frac{d}{l}$, that is, the crossed rods that make up the mat may properly be more numerous and more closely spaced in a thick slab than in a thin one, thus furnishing more effective co-action of steel and concrete in thick than in thin slabs.

In its present form Equation (2) is not convenient for numerical calculations, because the value of w itself depends on d. It will be

Mr. Eddy.

more convenient to express d as a function of w_0, the live load. Write Equation (2) in the form,

$$d = 0.024\, l\, \sqrt{w_0 + w_1}$$

by the help of the equation

$$w = w_0 + w_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

and eliminate

$$w_1 = 12.5t = 12.5\ (d + 1.5)$$

by assuming the weight of a cubic foot of concrete to be 150 lb., or 12.5 lb. per in. of thickness per square foot.

Then,

$$d^2 = (0.024\, l)^2\ (w_0 + 12.5\, d + 18.75).$$

Solve this quadratic equation and find,

$$d = 0.00375\ l^2 + 0.024\ l\ \sqrt{(w_0 + 18.75 + 0.0225\ l^2)} \ldots\ldots (8)$$

Table 2 has been computed from Equation (8). Now, if the value of the divisor in Equation (3) is assumed to be $a = 25$ at mid-span of the panel, as recommended in the report, then, by Equation (6), we find the steel ratio, $p = 0.0048$, throughout the entire table, regardless of $\frac{d}{l}$. It is apparent that the thickness found in Table 2 is too great at the larger spans and loads, so much so as almost to prohibit the use of flat slabs for the larger loads and spans figured in the table, but it is evident that this thickness may be reduced by increasing p somewhat with $\frac{d}{l}$.

The effect of this increase of p with $\frac{d}{l}$ will evidently be to produce a proportionate decrease of the dead load and of the thickness of the slab at the larger values of w_0 over that at the smaller values of w_0.

TABLE 2.—EFFECTIVE THICKNESS OF FLAT SLABS.

$d = 0.00375\ l^2 + 0.024\ l\ \sqrt{(w_0 + 18.75 + 0.0225\ l^2)}$ inches;
l = span, in feet; w_0 = live load, in pounds per square foot.

Span, in feet.	$w_0 = 100$	200	300	400	500	600
14	4.46	5.75	6.78	7.64	8.42	9.13
16	5.24	6.72	7.87	8.87	9.75	10.56
18	6.05	7.71	9.02	10.13	11.13	12.03
20	6.92	8.74	10.19	11.42	12.52	13.53

28	10.78	13.27	15.26	16.99	18.50	19.89
30	11.86	14.49	16.62	18.45	20.07	21.57
32	12.98	15.77	18.04	19.98	21.71	23.29

With the view of finding a simple approximate expression for d that will give values of d more nearly in accordance with the results of good practice than those obtained from Equation (4) or from Table 2, it is to be observed that, for any given span, l, Equation (8), regarded as a quadratic expressing the relation between the variables, d and w_0, taken as co-ordinates, represents a parabola. The part of the curve in question ranges from $w_0 = 100$ or less, to $w_0 = 600$ or more. In Fig. 10 the values of d in this range are plotted for $l = 20$ ft. Similar curves occur for other values of l. Mr. Eddy.

Suppose that the effective thickness for two different loads as, for example, at P_1 and P_2 in Fig 10, were sufficiently well ascertained by a consensus of good practice to be supposed to be known, then it would be possible to obtain an equation for a straight line through those two points that would give values of d for those and other loads, which might be more nearly in accord with good practice than those given by the parabola. Such an equation of relation between the effective thickness and the live load has been derived in what follows.

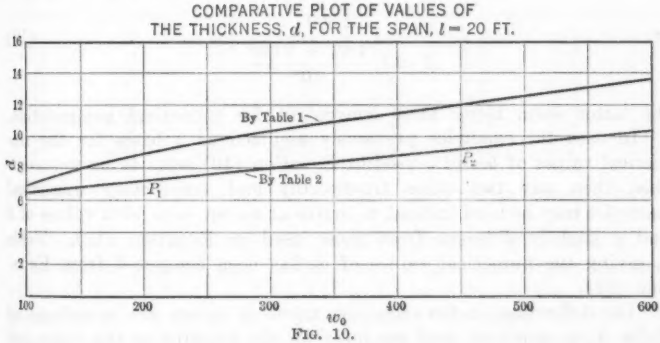

FIG. 10.

The equation for d through P_1 and P_2 may then be written in the form,

$$d = l\,\frac{w_0 + b}{c} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which l is the span, from center to center of supports, in feet, and w_0 is the total design working load, in pounds per square foot. The total thickness is

$$t = d + 1.5 \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

in which, if d is the effective depth of the centers of gravity of the steel below the compression surface of the concrete, 1.5 in. is the remaining part of the total thickness, including one-half of the layer of steel and its fire-proof covering. In the report this is taken as 1.5 in., of which the fire-proofing is required to be 1 in. in the clear.

Mr. Eddy.

In Fig. 10 the two points, P_1 and P_2, at which it was assumed that the two corresponding values of d were known, were both for the same span, l, but the values of the constants, b and c in Equation (9), can be determined equally well in case the known values of d correspond to any different known values of l and w_0 whatever. For example, assume that it is known from experience that, for a 17-ft. panel and a design live load of 200 lb. per sq. ft., the total thickness, $t = 7.6$ in., nearly, and for a 23-ft. panel and a design load of 400 lb. per sq. ft., $t = 11.6$ in., nearly. Substituting these values in Equation (9), gives the following equations from which to determine the values of b and c:

$$\left.\begin{aligned} 7.6 - 1.5 &= 17\ \frac{200 + b}{c} \\ 11.6 - 1.5 &= 23\ \frac{400 + b}{c} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots (11)$$

Hence, $b = 700$ and $c = 2\,500$, nearly, and Equation (9) becomes

or,

$$\left.\begin{aligned} d &= l\ \frac{w_0 + 700}{2\,500} \\ d &= l\ \frac{4\,w_0 + 2\,800}{10^4} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots (12)$$

the latter form being more convenient for numerical computation.

In case the examples previously assumed as a basis for the numerical values of b and c used in Equation (12) seem to be unacceptable, then any two other trustworthy and satisfactory numerical examples may be used instead, to arrive at an equation with values of b and c slightly different from those used in Equation (12). Table 3, giving the numerical values of d, has been computed from Equation (12).

The differences in the successive numbers in any row or column of Table 3 are constant, and are noted in the margins at the right and bottom of the table, so as to admit of ready interpolation and exterpolation by proportional parts, which, in this case, is exact and not merely approximate. If, in Equation (12), w_0 and l are regarded as rectangular co-ordinates in a horizontal plane, and d is erected perpendicular to it, the locus of the extremity of d will be a hyperbolic paraboloid which by its height will represent graphically the thickness of the slab. The numbers at the top and left of Table 3 measure such co-ordinates in the plane of the paper, and the numbers in the body of the table express the heights to be laid off at the positions where the numbers are written. The graphical surface thus constructed is a doubly-ruled surface such that a vertical section of it, for any given constant value of either w_0 or l, will be a uniformly sloping straight line.

Mr. Eddy.

The total thickness of the slab will be obtained, as in Equation (10), by adding to d one-half the total thickness of the layers of reinforcing steel plus the thickness of the fire-proofing, which all together may be either more or less than the average value of 1.5 in. recommended in the report.

The values of d in Table 3 are such as to make the thickness, t, throughout the entire table fall within the limit of one thirty-second of the span, as recommended in the report, excepting only the last number at the bottom of the first column, that is, $t = 10.24 + 1.5 = 11.74$, which is $\frac{1}{4}$ in. below the assigned limit.

TABLE 3.—Effective Thickness of Flat Slabs.

$$d = l\,\frac{4\,w_0 + 2\,800}{10^4} \text{ inches;}$$

l = span, in feet; w_0 = live load, in pounds per square foot.

Span, in feet.	$w_0 = 100$	200	300	400	500	600	Δ
14	4.48	5.04	5.60	6.16	6.72	7.28	0.56
16	5.12	5.76	6.40	7.04	7.68	8.32	0.64
18	5.76	6.48	7.20	7.92	8.64	9.36	0.72
20	6.40	7.20	8.00	8.80	9.60	10.40	0.80
22	7.04	7.92	8.80	9.68	10.56	11.44	0.88
24	7.68	8.64	9.60	10.56	11.52	12.48	0.96
26	8.32	9.36	10.40	11.44	12.48	13.52	1.04
28	8.96	10.08	11.20	12.32	13.44	14.56	1.12
30	9.60	10.80	12.00	13.20	14.40	15.60	1.20
32	10.24	11.52	12.80	14.08	15.36	16.64	1.28
$\Delta =$	0.64	0.72	0.80	0.88	0.96	1.04	

It will be noticed that Tables 2 and 3 give practically identical values of $d = 4.5$ in., or $t = 4.5 + 1.5 = 6$ in., at the upper left corner, where $l = 14$ ft., $w_0 = 100$ lb.; and at the upper right and left corners the values of d in Table 2 exceed those in Table 3 by about 25%, and at the lower right corner by nearly 50 per cent. These enormous differences are due to the increase in the value of p with $\frac{d}{l}$ involved in Equation (5), when a is constant.

When the value of $a = 25$ is used, that necessarily implies that the slab has steel enough in one direction to carry the entire load without any stress in the steel at right angles thereto, whereas, in fact, in an inside panel, the steel in both directions acts simultaneously, which requires $a = 50$, and not $a = 25$. This fact will reduce the value of p to one-half that previously found.

The steel ratio derived from Equation (5) is:

$$p = \frac{w\,l^2}{a\,f_s\,j\,d^2} = \frac{(w_0 + 12.5\,d)\,l^2}{16\,000 \times 0.9\,a\,d^2} \quad \ldots\ldots\ldots\ldots (13)$$

Mr. Eddy.

which gives the range of values of p, shown in Table 4. This table gives the numerical value of the ratio of the cross-section of the steel to the concrete at mid-span, in order that, when $a = 25$, the steel will resist the entire applied moment as in a beam, or, when $a = 50$, the steel will resist one-half of that amount, as in a two-way slab. Any intermediate values of l and w_0 may be found correctly from this table by simple interpolation of proportional parts.

TABLE 4.—VALUES OF STEEL RATIO, p, BY EQUATION (13).

	IF $a = 25$		IF $a = 50$	
	$w_0 = 100$	$w_0 = 600$	$w_0 = 100$	$w_0 = 600$
$l = 14$	0.0047	0.0073	0.0024	0.0036
$l = 32$	0.0067	0.0083	0.0034	0.0042

These values of p show that Table 3 requires no excessive steel ratios, either at mid-span or at panel margins, where, since the values of a will be about one-half those at mid-span, the values of p will be about twice as great.

In obtaining the values of d in Table 3, no allowance has been made for any reduction of span by reason of size of capitals. In order to make such allowance, it will be sufficient to assume that l is the effective span, instead of the actual span, and use it as the tabular span for finding d in Table 3.

It will now be in order to find out, in case slab thicknesses in accordance with Equation (9) and Table 3 are adopted, whether either the compressions in the concrete will be excessive, or the deflections of the slab will be greater than is permissible. For, if neither of these things occurs, then we have established the admissibility of these thicknesses, which are less than those found by Equation (1) and Table 2, and, hence, these latter will not be actual minimum values, but should be replaced by other smaller values found from Equation (9). The compression in the concrete is to be found from the common formula, $f_c = \frac{f_s k}{n(1-k)}$, in which k must be less than 0.4, and probably does not exceed 0.3; and we may assume $f_s = 16\,000$, and $n = 15$, so that the unit stress, f_s, does not exceed 700 lb., and probably is not more than 500 lb., at any point, unless at the edge of the capital, at which point a special investigation may be necessary. This shows that, in general, the compression in the concrete should not be regarded as excessive.

Mr. Eddy.

An expression for the deflection, z, at the panel center of a flat slab has been found to be:

$$z = \frac{W L^3}{4.75 \times 10^{10} d^2 A_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots (13)^*$$

in which $L = 12\ l$ is the span, in inches (not feet), and A_1 is the cross-section of a side belt.

Now,

$$A_1 = \frac{1}{2} A = \frac{W L}{2 f_s a j d},$$

which last was obtained by equating applied and resisting moments as in Equations (3) and (4). Substitute this value of A_1 in Equation (13), and assume $f_s = 16\,000$, $a = 25$, $j = 0.9$, and let the slab be as thin as permissible, namely, $\frac{L}{d} = 32$. We then have the largest possible relative deflection for a unit steel stress of 16 000 lb. Then, the relative deflection,

$$\frac{z}{L} = \frac{2 f_s j a L}{4.75 \times 10^{10} d} = \frac{1}{2\,060} \quad \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

This relative deflection is so small that it would permit a test load of more than 2.5 times the sum of the design load plus the dead load, without causing $\frac{z}{L}$ to exceed $\frac{1}{800}$, provided the steel were not thereby stressed beyond its elastic limit, which, in this case, would have to be at about 40 000 lb. per sq. in. Smaller values of $\frac{L}{d}$ than 32, such as occur throughout almost the entire Table 3, will give smaller values of $\frac{z}{L}$ than the limiting value computed in Equation (15). On the other hand, although a value of a larger than 25 would have an effect to offset the smaller values of $\frac{L}{d}$ and so to increase $\frac{z}{L}$, yet the observed values of f_s are invariably much smaller than those computed by Equation (14), which serves actually to reduce the value of $\frac{z}{L}$ at least to that found by Equation (15). It follows, consequently, that values of d as small as those in Table 3 may be used with safety, and that values as large as those in Table 2, as prescribed by Equations (1) and (2), are not a minimum, and it has been further shown that they are unnecessarily large.

* See "Concrete Steel Construction", Eddy and Turner, (71), p. 204.

Mr. Eddy.

The report recommends minimum total thicknesses that may be written as follows:

$$\left.\begin{aligned} &\text{For a slab without a drop, } t = 0.024\, l\sqrt{w} + 1.5 = d + 1.5 \\ &\text{For slab with drop, } \quad t = 0.02\, l\sqrt{w} + 1 = \frac{5}{6}\, d + 1 \\ &\text{For the drop itself, } \quad t = 0.3\, l\sqrt{w} + 1.5 = \frac{5}{4}\, d + 1.5 \end{aligned}\right\} \ldots\ldots(16)$$

and, further, that the width of the drop is $0.4\ L$, so that its area will be $(0.4\ L)^2 = \frac{L^2}{6}$, nearly. Hence, the total volume, in cubic inches, of a panel without a drop would be:

$$v = (d + 1.5)\ L^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(17)$$

but the volume of a panel together with a drop would be:

$$v = \left(\frac{5}{6}\, d + 1\right)\frac{5}{6}\, L^2 + \left(\frac{5}{4}\, d + 1.5\right)\frac{L^2}{6}, \text{ nearly, or}$$

$$v = \left(\frac{65}{72}\, d + 1.1\right)\, L^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(18)$$

From this it is evident that the report discriminates against the flat slab without a drop and in favor of the slab with a drop by making the latter so much thinner that the total volume per panel is less. In the writer's opinion such discrimination is without justification in theory or practice. In his opinion, in order to make the formulas for the thicknesses of slabs with a drop comparable with those without a drop, the volume of the former should be at least as great as the latter. With this in view, it will be necessary, in order to have the drop 50% thicker than the rest of the slab and its area $= \frac{L^2}{6}$ to write for the thickness of a slab with a drop,

$$\left.\begin{aligned} &t = 0.022\, l\sqrt{w} + 1.5 = \frac{11}{12}\, d + 1.5 \\ &\text{and for the drop itself,} \\ &t = 0.0033\, l\sqrt{w} + 1.5 = \frac{11}{8}\, d + 1.5 \end{aligned}\right\} \ldots\ldots\ldots\ldots(19)$$

Hence,

$$v = \left(\frac{11}{12}\, d + 1.5\right)\frac{5}{6}\, L^2 + \left(\frac{11}{8}\, d + 1.5\right)\frac{1}{6}\, L^2$$

or, $\quad v = (d + 1.5)\ L^2$, nearly.

The reason for the foregoing statement is this: In the case of a given uniform loading, the numerical sum of the bending moments at mid-span and one margin is constant, but the sub-division of this

Mr. Eddy.

constant total moment between mid-span and margin depends on the structure of the slab, as follows: Either the line of inflection in the slab occupies a position fixed by the simultaneous dip of the reinforcing rods as they drop below the neutral surface, or it is undetermined, due to the irregular dipping of the steel, and, in that case, is determined only by the relative stiffness of the columns and of the panel at the margin, as compared with that at mid-span. The report does not contemplate any fixed lines of inflection, for it makes express provision for irregular dipping of steel rods. However, it recommends that steel be provided to resist moments of certain given magnitudes at mid-span and margin separately, regardless of the presence or absence of a drop. If that recommendation is to be adopted, the suspended portion of the panel must needs be just as thick in case of a drop as without it. The only excuse for its being made thinner with a drop would be that the columns and the cantilever portion containing the drop had been made stiffer and the cantilever made larger thereby, so that the lines of inflection were thereby made to occupy positions somewhat more distant from the columns than in the case where there is no drop. This would require the steel over the drop to be kept near the top of the slab for a greater distance than in a plain flat slab, and would also require larger and stiffer columns to resist the unequalized moments, but would hardly permit the total volume of the panel to be decreased, as has been done in the report.

It is still an unsolved problem to determine the economical relative sizes of the suspended portions of the panel and of the cantilever, and the relative stiffness of the columns, as well as the manner of distribution of the resisting moments across the margins of the panels. On the solution of this problem evidently no light has been shed by the recommendations of the report, since it recommends a difference in thickness without any difference in the resisting moment—a recommendation hard, if not impossible, to justify.

Equations (19) for thicknesses of slab and drop to replace those recommended in the report, assume in effect that the cantilever portion of a slab with a drop will be slightly larger than without a drop, but do not proceed to such unjustifiable lengths as the corresponding expressions in Equations (16) given in the report, which wholly ignore the redistribution of the constant total moment between mid-span and margin and the increase of that part of the unequalized moment distributed to any column due to decreasing the stiffness of the panel at mid-span.

In adopting Equations (19) for the thickness of the slab and drop, it is understood that the values of d which are to be inserted, in order to obtain minimum values of t, are those obtained from Equation (12) and Table 3, although the foregoing criticism of Equations (16) is

Mr. Eddy.

equally valid were we to adopt as correct the values of d derived from Equation (8) and Table 2.

2.—Flat Slabs as Statically Indeterminate Structures.—In the second place, the writer objects to the adoption in the report of any theory of flat slabs as correct, which assumes them to be statically determinate structures, because they cannot be so regarded. The report, however, on page 1138, refers to the paper of John R. Nichols,* Jun. Am. Soc. C. E., as affording an approximate basis for its formulas. Now, any assumption of the validity and applicability of statical analysis to continuous flat slabs is incorrect, and leads to erroneous results, just as much as in the case of continuous beams or of any other indeterminate structures.

Any structure in which the magnitude or distribution of the stresses in any part of it undergoes any alteration by varying the rigidity of any of its members or elements is statically indeterminate. Hence, the principles of statics cannot be assumed to be applicable to such a structure unless there is definite proof that the statical principles sought to be applied are actually valid for the case in hand, so that it is beside the mark to adduce any statical limitations or requirements in flat slabs, such as are adduced in the report, because statical principles must here be subordinated to the principle of rigidities, which is the guiding principle in all indeterminate structures.

That a flat slab continuous over an unlimited array of separated supports is an indeterminate structure according to the above definition is evident from comparing the distribution of the stresses across the sides of the panels, due to the bending moments in a slab having most of the reinforcing steel concentrated in belts passing over the supports, with the distribution of the stresses across the sides of the panels where this is not the case, as it is not in the crown-sheet of a steam-boiler, for example. For, in the former case, the stresses across the sides due to the bending moments are largely concentrated at and near the supports, but it is far otherwise in the crown-sheet, which is supported on stay-bolts that pass through holes in the sheet, which completely destroy the radial resistance to bending at the supports. By reason of this distribution of the rigidity in the crown-sheet, the entire resistance to bending across any side of a panel is afforded by that part of the side lying between supports, and none of it is at the supports.

Statical principles, therefore, may be applied to flat slabs only after due inquiry and after it has been ascertained to what extent they may be applied to them. Statics and the principle of the lever are so ingrained in all reasoning about structures that the unconscious assumption of their applicability is likely to vitiate otherwise well-considered investigations of structures so complex in their interactions as inde-

* "Statical Limitations upon the Steel Requirement in Reinforced Concrete Flat Slab Floors", *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 1670 (1914).

terminate structures must necessarily be, and great care must be exercised in order to avoid the conclusions that inevitably follow from yielding to the insidious temptation unconsciously to make this assumption. The following unavoidable conclusion, therefore, may be formally stated: Mr. Eddy.

Proposition I.—Continuous flat slab floors on separated supports are indeterminate structures subject to the law of relative rigidities and its corollary, the law of least work.

In any indeterminate structure the relative rigidities of its parts control the distribution of the stresses in it strictly in proportion to the relative rigidities of the paths by which those stresses are carried, so that the greatest total stresses occur wherever the structure offers the greatest total resistance to deformation.

The steel reinforcement in a slab affords the principal resistance to tensile stress, and hence the total tensile resistance is, in general, where the cross-section of steel is greatest. Consequently, the distribution of the tensile stresses will in general be controlled by the quantity and position of the steel in the slab.

3.—Shearing Stresses in Flat Slabs.—Equilibrium requires that the total vertical shearing stress across the perimeter or margin of any panel shall be equal to the sum of the total live load resting on the panel added to the weight of the panel itself. The perimeter of the panel may be taken approximately at the sides of the rectangle the corners of which are at the four adjacent column centers, but it may be found somewhat more exactly by replacing parts of this rectangle near the columns by parts of the perimeters of the column capitals for 90° around each column center.

Shearing stresses transmit loads horizontally by the help of the bending moments which they bring into play, and they re-apply those loads undiminished in total amount at the supports at some distance horizontally from their initial positions.

In order to discuss this matter mathematically, designate the total uniformly distributed load on one panel by W, then, in case of a square panel loaded uniformly and supported at its four sides by walls or equal girders, the total vertical shear across a section close to one side is $\frac{1}{4}W$, as is evident either by symmetry or by the principle of the equal rigidities of the possible paths, lying in two directions at right angles to each other, by which the load may be carried to the supports.

Again, take the case of a single inside panel of any equally loaded panels supported on columns with square capitals, the edges of which are parallel to the sides of the panels; then, on the same principle, it is evident that the vertical shear across each side of each capital is $\frac{1}{4}W$. Now, whatever may be the shape of the perimeter of the capitals, the sections on which vertical shear occurs may be taken to be made up

Mr. Eddy.

of an infinite number of successive elementary vertical faces all of which are parallel either to one or other of the sides of the panel. Then the total shear on all the vertical faces on one side of a capital, which are parallel to one side of a panel, is $\frac{1}{4}W$. This may be regarded as equivalent to saying that, whatever shape the perimeter of the capital may actually have, it can be assumed without material error for the purposes of computation to be replaced by a square capital.

It will be noticed that the intensity of the vertical shear across the perimeter of the panel is distributed in a very different manner, in the case of supporting walls on four sides, from its distribution across the edges of square capitals, in the case of supporting columns, for, in the latter case, the shear is all concentrated at the perimeter of the capitals and is zero at the other parts of the perimeter of the panel between capitals, although the total amount in either case must be equal to the panel load, W.

This concentration of shear is brought about by the bending and deformation of the slab, in which a shallow saucer-shaped hollow is produced around each panel center, while around each column center the slab is bent into the shape of an inverted saucer. The stresses accompanying these deformations effect the distribution of the shears just mentioned, as well as that of the bending moments also, a matter which will be treated later.

In case of wall supports on the sides, slab deformations are very different from this, as they produce the distribution of shears and moments that occur at the walls, which are very different from those at the perimeter of the capitals, a matter that has been treated by the writer elsewhere.* In all cases, the distribution of the vertical shears depends on, and is controlled by, the relative rigidities of the various parts of the perimeter and supports, as expressed by their capacity to resist vertical forces without yielding. Any subsidence or yielding of a support or any part of it will alter the distribution of shears that otherwise would take place and reduce their intensity, and any inequalities in the resistance of the material at the perimeter of a capital will cause corresponding inequalities in distribution of the shears.

Again, consider a single square panel that is one of a single tier of equal square panels which constitute a wide beam and are supported on a succession of equi-distant transverse parallel walls or rigid girders across the tier. In this case no saucer-shaped hollows are produced by the load, for simple flexure alone occurs in such a case, and the deformation is designated as cylindrical, meaning thereby that the surface produced by flexure is a ruled surface such that any sections of it by vertical planes parallel to the wall supports are horizontal straight lines parallel to the walls. In this structure the entire shear-

* "Concrete-Steel Construction", Eddy and Turner, p. 285.

ing rigidity at the sides of a panel is at the walls, and is zero at the two unsupported sides. The total shear at each supported side is $\frac{1}{2}W$ and the total shear at any parallel vertical section between the walls will be twice that occurring at the corresponding section of an inside panel of a continuous slab of several tiers of panels on separated supports, such as was considered previously. As just stated, this shear of $\frac{1}{2}W$ is due to the fact that there are no supporting resistances or rigidities at the two unsupported sides of this panel. Mr. Eddy.

This fundamental difference in the distribution of the total vertical shear at or across panel-wide sections in those two cases is of the utmost importance in the theory of flat slabs, because, owing to the fact already stated that a given panel load, W, can produce a total shear at the perimeter no greater than W, not only are the total shears in sections parallel to the sides of the panels of flat slabs on separated supports 50% less than in the wide beam structure just described, but, by reason of the necessary relation existing between the shears and the bending moments, the total applied bending moment produced at any panel-wide section of an inside panel is likewise reduced to 50% of that which would be produced if the total load were carried, as in the beam, by moments across that section and sections parallel to it, and none of it was carried by moments across sections at right angles thereto. Now, since in a continuous slab on separated supports equal rigidities occur in two sets of sections at right angles to each other, both must act at the same time, and each does 50% only of that which it would do in the absence of the other. In other words, since the shears in the sections parallel to either one of the sides of the panels in a continuous slab on separated supports are those that arise from a uniform panel load of $\frac{1}{2}W$, and equal shears also occur in sections at right angles thereto, it follows that the applied bending moments across each of the set of panel-wide sections parallel to the sides of such a panel are those arising from a uniformly distributed panel load of only $\frac{1}{2}W$, instead of a load, W, as was the case in a beam.

However, a wall panel in a flat slab floor that rests on a side-wall of the building at one side of the panel is prevented by the wall from having any deflection at that edge, so that the curvature of the panel under load is more nearly cylindrical near the wall than it would be with separated column supports at the edge. This makes the action of the panel more nearly like that of a wide beam with one end resting on the wall. In other words, the total shear in a section close to the wall will be greater than $\frac{1}{4}W$, but less than $\frac{1}{2}W$, while the total shear in a section at right angles to the wall and at the edge of the panel will be less than $\frac{1}{4}W$. The applied bending moments in these two directions in the panel will be such as to correspond to those shears.

An outside panel, however, the outer edge of which is supported on separated columns only, with no additional girder or stiffening

Mr. Eddy.

along its outer edge, undergoes a greater deflection at the outer edge between supports than at other edges, and the total shear at a section near the outer edge is less than at corresponding sections near the other edges of the panel, and needs additional stiffening in the slab, either at the outside edge or parallel thereto. The effect of this kind of column support is to make the total shear in a section near the outer edge of the panel less than $\frac{1}{2}W$, while it makes that in a section of the panel at right angles thereto and near the side of the panel greater than $\frac{1}{2}W$. Corresponding changes occur in the total applied bending moments in the two directions in these panels. This last kind of outside panel with others contiguous thereto takes on more or less of the properties of a beam along the outside of the slab in which it differs materially from an outside panel resting on a wall, which last, it was seen, had some of the properties of a beam with an end at the wall.

A comparison of the two preceding paragraphs shows that outside panels supported at the edge of the slab on an outside row of columns may be designed so that their action will resemble closely that of the inside panels. In order that this may occur, the reinforcement at the outside edge must be such that at the heaviest loads to which it is subjected the deflections will be the same at mid-span between the columns at the edge as occur under these loads at mid-span between interior columns. These identical deformations will ensure nearly equal shears and bending moments in outside and inside panels, because the saucer-shaped deformations will be nearly the same in each.

4.—Applied Bending Moments in Flat Slabs.—It is a well-known proposition of beam theory that the sum total of half the numerical values of the applied negative bending moments at the ends of any span of length, L, plus the numerical value of the positive bending moment applied at mid-span, all arising from a uniformly distributed load, W, amounts to $\frac{WL}{8}$, whether the span is a simple one with end supports merely, or is continuous, or partly so, and this without regard to the loading or absence of loading on other spans of the beam. This proposition holds true regardless of the relative magnitudes of the moments of inertia of the beam at its successive cross-sections by which the relative rigidities of the beam in resisting the applied bending moments is expressed. It likewise is independent of the rigidity or lack of rigidity of the supports or their connections with the beam in resisting applied bending moments. The proposition, therefore, considers such a beam as an indeterminate structure to which the principle of rigidities applies in determining how the total moment, $\frac{WL}{8}$, is distributed between mid-span and ends. It will be convenient to designate this constant quantity, $\frac{WL}{8}$, as the total applied bending moment in the

span, L, due to the uniform load, W. A proof of this well-known proposition may be found, among other places, in a paper by the writer.* Mr. Eddy.

In accordance with the conclusions already reached in this discussion, the total applied bending moment in each direction parallel to the sides in a panel of a continuous slab on separated supports depends on the part of the load that is transmitted by the shears in that direction, so that, in an inside panel of such a slab, only one-half of the bending moment would be applied in each direction, and therefore the sum total of the numerical value of the positive applied bending moment across a mid-section parallel to one side added to the numerical value of the negative applied bending moment across that side is only $\frac{WL}{16}$. In any case, the sum, as above specified, of the applied bending moments in the two spans lying at right angles in any panel would together have the constant value, $\frac{WL}{8}$.

In view of this, and disregarding for the instant the effect of the size of the supports, we will state:

Proposition II.—In any square panel, inside or outside, of a continuous flat slab on rows of separated supports placed at successive distances of L from each other and carrying a total uniformly distributed panel load, W, the sum total of the numerical values of the positive applied bending moments acting across the two panel-wide mid-sections drawn at right angles parallel to the sides, added to half the sum total of the applied bending moments acting across the four sides of the panel, is equal to the constant quantity, $\frac{WL}{8}$.

This proposition may be readily demonstrated for an inside panel in which the rigidities are equal and symmetrical about both of the mid-sections. For,

Let S_x represent the total vertical shear across a panel-wide section at a distance, x, from the panel center;

and let M_x represent the total applied bending moment at the same section.

Then, $dM_x = S_x dx$, for this equation expresses the necessary fundamental relation of shear to applied moment along x.

Similarly, for sections at right angles to this, the corresponding equation may be written:

$$dM_y = S_y dy.$$

* "A Further Discussion of the Steel Stresses in Flat Slab Floors", *Proceedings*, Am. Concrete Institute, 1916, p. 284.

Mr. Eddy.

Now, combining sections at right angles to each other and at equal distances from the panel center at which $x = y$, the sum of the two vertical shears across these sections is equal to the total load between either of them and the mid-section at $x = 0$, or at $y = 0$; that is, when $x = y$, we have $S_x + S_y = \frac{Wx}{L}$, in which $\frac{W}{L}$ is the total panel load per unit of width or length of panel.

In case of equal rigidities in directions at right angles, at equal distances, $x = y$, from mid-section, we have $S_x = S_y$, but not in case of unequal rigidities. In any case, at $x = y$ we have $S_x + S_y = \frac{Wx}{L}$.

Hence, by addition, at $x = y$,

$$d\,(M_x + M_y) = (S_x + S_y)\,d\,x = \frac{W\,x\,d\,x}{L},$$

and integrating between $x = 0$ and $x = \frac{1}{2}\,L$,

$$(M_x + M_y)_{x\ =\ y\ =\ \frac{1}{2}\,L} - (M_x + M_y)_{x\ =\ y\ =\ 0} = \frac{W\,L}{8},$$

that is, the excess of the sum total of the positive moments across the two panel-wide mid-sections drawn at right angles to each other over the sum total of the negative moments across two sides mutually at right angles is $\frac{W\,L}{8}$. This excess, however, is the sum of the numerical values of these moments, which is the result stated in Proposition II. This holds true in general in case of unsymmetrical rigidities, although the demonstration is less simple for the more general case.

The distribution of the bending moment along each panel-wide section depends on the relative resistance to bending of the several parts of that section, as was pointed out, for example, where the bending resistance of the crown-sheet of a boiler was considered. The sub-division of the total applied bending moment, $\frac{W\,L}{8}$, between the two directions at right angles, however, depends not only on their relative resistances to bending moments at these sections, but also on their capacity to resist vertical shears as well.

As a result of the preceding investigation, we have consequently established the following:

Corollary.—In a square interior panel under a uniform load, W, the total numerical value of the positive bending moment at a mid-section, added to the total numerical value of the negative bending moment at an edge parallel to the mid-section, is only one-half of $\frac{W\,L}{8}$.

Disregarding for the instant the reduction of span due to the size of the capital, the report says: Mr. Eddy.

"Analysis shows that * * * the numerical sum of the positive moment and the negative moment at the two sections named is given quite closely"

by $\frac{WL}{8}$, when written in the notation used herein. This shows that, for an inside panel, the analysis adopted in the report would make the applied moments twice as great as has just been shown really to exist. It is stated in the report, however, that the use of moment coefficients somewhat less than those derived by this analysis is believed to be warranted, and the reason assigned for this is the tensile resistance of the concrete. How small the allowance to be made on this account is, may be estimated from the recommended coefficients of $\frac{1}{25}$ at mid-span and $\frac{1}{15}$ at a margin, the sum of which is practically $\frac{1}{9.4}$ in place of $\frac{1}{8}$, as given by analysis. It is clear, therefore, that the recommendations in the report practically require provision to be made, so far as resisting applied moments are concerned, sufficient to carry the entire load by resistance in one direction only and then require, in addition, that provision shall also be made to carry the entire load by resistance in a section direction at right angles to the first, when, in fact, one-half must be carried in each direction. It is perhaps unnecessary to remark that since moment magnitudes are of the nature of directed quantities, moments at right angles to each other are mutually independent of each other.

5.—Lines of Inflection.—As ordinarily understood, lines of inflection or lines of contraflexure are those lines drawn on the slab at which successive panel-wide sections of the slab cut out by vertical planes parallel to the sides of the panel change curvature from convex to concave, or *vice versa*. It is evident that since there are two such sets of panel-wide sections at right angles to each other, there must be two sets of lines of inflection crossing each other. There would also be other lines of inflection for any other sets of sections, as, for example, sections parallel to the diagonals, etc. Considering, however, for the present, only those lines of inflection arising from panel-wide sections parallel to the sides, and in order to arrive at a more complete understanding of them and their relations to the deformations of the panels, let us take, for the sake of simplicity, the case of a homogeneous uniform flat plate, such, for example, as a steel plate of indefinite extent, resting on rows of equidistant separated supports in square array, and let it be subjected to equal concentrated

Mr. Eddy.

loads, applied at the panel centers. Then, the upward resistance at each support is equal in magnitude to each of the concentrated loads. The top and bottom of the plate are then subjected to sets of forces which are alike in every particular except position and opposite direction, and the plate is bent in a perfectly symmetrical manner. On the surface of the plate draw lines parallel to the sides of the panels located half way between the supports and the panel centers. This will divide up the entire surface, checker-board fashion, into squares, the sides of which are one-half the distance between supports. These lines will be the inflection lines of the plate. The squares over the supports will be convex upward, those in which the panel centers lie will be convex downward, the others will be saddle-shaped. The bending moments across the lines of inflection will be zero.

If, now, the loading is supposed to be changed from concentrated loads to a uniformly distributed load, the curvatures in the central part of the panel will not be so sharp as in the case of concentrated loads, and the lines of inflection will thereby be removed slightly toward the supports, but will still remain straight. If, however, the plate is replaced by a slab which is reinforced so as to be stiffer over the supports than elsewhere, that will move those parts of the lines of inflection which are around the supports farther away from the supports, so that they no longer will be straight. If, in addition, the stiffness of the slab across the saddle-shaped areas is made less than elsewhere, those parts of the lines of inflection which lie around the panel centers will move nearer to the sides of the panel. In such a slab, the lines of inflection will divide up the area of the slab irregularly, in checker-board fashion, into areas which are only roughly rectangular, in which the convex and concave areas have bulging sides, but the saddle-shaped areas will have hollowing sides. The sides of these irregular areas are the *loci* of no bending across them along sections perpendicular to the sides of the panel, and, consequently, of no bending moment in that direction; but that does not necessarily signify that the stresses in either the steel or the concrete is zero across these lines. This is a fact, because the steel rods which are known to be in tension both in the tension areas around the supports and in those around the panel centers, are, no doubt, in tension throughout their entire lengths, not only in the tension areas, but across the lines of inflection as well, which fact would require the entire cross-section of the concrete to be in compression across lines of inflection, because, at any vertical section subjected to bending moment only, the sum of the tensions and compressions must be numerically equal.

From what has been already stated, it is evident that the location of the lines of inflection is fixed by the rigidity of the slab, and is

largely within the control of the designer, so that it will be practically where the steel dips down below the neutral surface of the slab as it passes from the tensile zones at the top to those at the bottom of the slab. Mr. Eddy.

Now, compare this with a design in which all the steel does not dip down at the same line. The effect of this would be to cause the lines of inflection to lie at one place for one concentration of loading and at another place for a different concentration.

The difference of action between these arrangements of steel is like that existing between the cantilever bridge and the continuous bridge of several spans. In the continuous bridge, the inflection point moves along the bridge to some extent as a train crosses, whereas, in the cantilever bridge, the point of zero moments is located definitely by a joint at the junction of the cantilever and suspended span. The same advantages are secured in flat slabs as in bridges by fixing the length of the cantilever as well as the relative size of cantilever head and suspended span by having all the steel dip down at a given line, for this arrangement reduces the bending resistance at the line so as to make it the line of inflection at all times.

It is evidently possible to make the cantilever extend out from the supports to any distance, even as far as mid-span, by sufficiently reinforcing the top of the cantilever throughout and, at the same time, reducing the resisting moment of inertia of the section at the edge of the cantilever. Now, this will be practically accomplished by making all rods dip together at the same line of inflection predetermined in such position as to separate the total applied bending moment of the panel into such parts as may be desired. This may be formally stated in the following:

> Proposition III.—In a continuous flat slab on separated supports the relative size of the cantilevers over the supports and the suspended spans within the panels, as well as the relative magnitudes of the total applied bending moments across the panel-wide sections at mid-span and at the sides of the panel, may be controlled by the location of the dip in the reinforcing rods across the neutral surface at predetermined lines of inflection.

Now, it is recommended in the report to have the steel dip down one part of it at one distance from the edge of the panel and another part at another distance, thus making the position of the lines of inflection absolutely impossible of determination for any loading, and different for different dispositions of load, and also making the subdivision of the total moment between mid-span and margin uncertain. The actual subdivision will then depend on several factors besides the positions where the steel dips down, such as the relative moments

Mr. Eddy.

of inertia of the cross-sections at mid-span and margin, and the stiffness of columns, etc. The recommendation is bad in principle and more to be honored in the breach than in the observance, because making the rods dip down at different points renders bending moments indeterminate which, otherwise, would be determinate. This is discussed somewhat more in detail in the next section.

6.—Column Rigidities and Relative Slab Rigidities across Panel-wide Sections, as Affecting the Sub-division between Mid-Span and Margins of the Total Applied Bending Moment in the Panel.—In any beam of constant moment of inertia, fixed horizontally at the ends and uniformly loaded with a total load, W, the applied bending moment at mid-span is $\frac{W\,L}{24}$ and at each end is $-\frac{W\,L}{12}$. In case the moment of inertia or resistance to bending is made greater at and near the ends than elsewhere, the numerical value of the applied bending moment at each end will be increased at the expense of that at mid-span, but their numerical sum will still be $\frac{W\,L}{8}$. If, however, the restraint at the ends is reduced so as to be insufficient to fix them horizontally at the supports, the positive moment at mid-span will increase numerically, while the numerical value of the negative moment at each end will be decreased by the same amount. Similar principles apply to the moments at panel-wide sections of inside panels of a continuous slab over separated supports, except that the uniformly distributed load in the case of the slab, which causes the applied moment in each direction, will be only one-half of the total panel load, W, as previously shown. The column supports of a continuous slab are not usually sufficiently rigid to afford perfectly horizontal restraint at the supports, but there seem to be clear indications that, under ordinary circumstances, the columns resist about one-half the unequalized bending moments at the supports. That, however, is partly dependent on the rigidity of the connections between the slab and the supports.

In order to obtain an outside estimate of the divergence between the effect of the complete restraint at the ends previously considered and free tipping over the supports, let us suppose a uniform beam of three equal spans resting on four supports, with a uniform load on the middle span only, but free to tip at all four supports. The theorem of three moments shows that, in this case, the applied moments at the support would be $-\frac{W\,L}{20}$, while that at mid-span would be about $\frac{W\,L}{13}$. If, however, the beam were fixed horizontally at its two ends, but could tip freely over the two intermediate supports, the amounts

over these would each be $-\frac{W\,L}{18}$, while that at mid-span would be about $\frac{W\,L}{14.4}$. These results, compared with those for the single span with fixed ends, show that, although lack of fixity at the ends of the span, L, might reduce the numerical value of the applied moment by one-third or more at the edges of the panel, at the same time it might nearly double the moment, $\frac{W\,L}{24}$, at mid-span, even when no account is taken of any additional effect due to increased stiffness, such as is usual at the edges of the panel. Mr. Eddy

As previously shown, the foregoing results for beams should be divided by two, in order to make them applicable to inside panels of continuous slabs of equal moments of resistance at mid-span and margin.

How little the results thus obtained can be reconciled with the recommendation in the report which proposes to use the coefficient $\frac{1}{15}$, at the margin and $\frac{1}{25}$ at mid-span, regardless of relative column and slab rigidities, is left to the meditation of the reader.

7.—*The Distribution of Bending Moments Across Panel-wide Sections.*—As already stated, in connection with the bending of the crown-sheet of a boiler, the distribution of the rigidities in any panel-wide section completely determines and controls that of the intensities of the resisting moments in that section. Bending moments are by-products and secondary phenomena in a beam or slab, and depend mathematically on the shear, which is, in fact, the primary action produced by the load. The rigidities which affect the distribution of shears are mostly independent of those which affect the distribution of the moments. The rigidities which control the distribution of the bending moments do this in two distinct ways, one is by the relative resistance across different parts of any panel-wide section, which determines the distribution and relative intensities of the stresses at the several parts of that section, the other is by the relative total resistances across the parallel sections at mid-span and margins of the panel, which determines the relative total moments across those sections. The effect of the latter has been considered previously.

We are concerned here, therefore, with the sub-division of the total bending moment at one margin of a panel into two parts, one part across the two middle quarters, or inner section of the edge as it is called, and the other across the rest of the margin, or the column-head sections. The only possible basis for any sub-division or partition of the total marginal moment between these sections of the margin must be some existing or assumed distribution of the resistances across

Mr. Eddy.

these sections. For, as already explained, the distribution of stresses will depend on the distribution of resistances. It should be noticed that, in case a distribution of stresses was found for a uniform plate by calculation, or by experiment, as was done by Trelease,* and then the slab was reinforced by belts of steel the resistances of which are made proportional to the stresses so found, the slab thus reinforced would no longer be one the rigidities of which were those of the original uniform plate, and the stresses in the slab would then be distributed in a manner very different from those in a uniform flat plate. So that any such basis for design is wholly illusory. This is also true regarding the subdivision of the total applied bending moment between the parts of the panel-wide section at mid-span.

The saddle-shaped deformations which occur at the sides of the panel directly between the column heads produce, in the top of the slab, tensions across the sides at mid-span and compressions parallel to the sides. These are stresses on vertical plane sections of the slab at right angles to each other, and express a state of stress in the material which may be expressed otherwise by saying that there are other vertical planes intermediate between these (inclined to them possibly at nearly 54°) on which the entire resultant stress is a shear horizontally along each plane, which increases in intensity according to its distance from mid-depth of slab.

The material of the slab effectively resists these shears, especially when it is well reinforced near mid-span of the sides, and such resistance, called into play by the load, helps to carry the load, as do all other resistances; but this is a kind of resistance additional to any occurring in any simple beam structure, and it enhances the resistance of this part of the slab above that of simple moment resistance just as truly as the circumferential and radial action of the steel does in the convex and concave areas. It is by the help of these saddle-shaped deformations that the distribution of rigidities across the sides effect a corresponding distribution of stresses, as may be seen from the following discussion.

Suppose that little or no tensile resistance existed in the top of the slab across the edge of the panel near mid-span; then the panel on each side of that edge would deflect more readily for that reason, and the deflections at the panel centers on either side of this edge would be greater than otherwise. This sag on each side and yielding to bending across mid-span of the edge would transfer the applied bending moments each way from this point and bring them to bear

* "The Design of Concrete Flat Slabs", by F. J. Trelease, *Proceedings*, National Assoc. of Cement Users, Vol. VIII, 1912, p. 218.

on the slab at and near the column heads. If, however, very rigid reinforcement is introduced across the edge at and near mid-span, it will resist the greater portion of the total bending moment across the inner section of the edge and relieve the tensile stresses across the column heads by just so much, and so prevent any necessity for piling much steel directly over the columns. At the same time it will reduce the central panel deflections as well. Until it is proved that steel across the column heads resists bending moments more economically than across the inner sections, any recommendations such as those in the report, following the Chicago ruling, and intended to control the distribution of the steel across the margin, etc., are contrary to good policy and an intolerable restraint on legitimate design. Mr. Eddy.

The truth of this last statement is evident from the following considerations. The intensities of compressive stresses across panel-wide sections must be distributed along those sections in a manner corresponding in the main with the distribution of the tensile stresses in the steel in these sections. In ordinary design, with steel belts massed across the supports, it has been frequently asserted that critical compressive stresses occur in the concrete around the column capitals. If this is true, it is due to the concentration of steel in the side belts, and can be obviated by such a disposition of the steel as to transfer a suitable fraction of the bending moments across the panel edges to the inner sections, and thereby relieve any excessive compressions in the outer sections. Any uncertainty which now exists respecting the existence of too large compressive stresses at right angles around the capitals can be thus removed, and the question of controlling the critical stresses in the concrete around the columns be thereby confined to the question of the vertical shearing stresses.

8.—Bending Moments Reduced by Size of Capitals.—In the next place, consider the distance by which the length of the span, L, between the column centers must be reduced in order to obtain a correct estimate of the effective span. How great such a reduction should be depends on several circumstances. In case the capitals are integral with the slab, and the columns perfectly rigid or nearly so, the effective span between capitals (each of diameter $= C$) would be $L - C$, and if all the reinforcing steel was to pass over these capitals, the length of the span would practically be $L - C$, while the panel load, W, would remain practically unchanged.

As a mean value, under ordinary conditions of flexibility of columns, etc., the mean effective span may be conservatively taken as $L - \frac{2}{3} C$, although this may be subject to change in special cases. This may be stated explicitly as:

Mr. Eddy.

Proposition IV.—When a correction for the size of capitals is introduced, the constant applied moment in the span, $\frac{W L}{8}$, becomes approximately

$$\frac{W L \left(1 - \frac{2 C}{3 L}\right)}{8}.$$

If the panel, however, is one of a tier of panels supported on a series of successive transverse walls, each of width $= C$, instead of on separated supports, the load, W, would also need to be reduced in the same ratio as the span, and the constant applied moment per span thus corrected would become

$$\frac{1}{8} W L \left(1 - \frac{2 C}{3 L}\right)^2,$$

due to an effective span, $L \left(1 - \frac{2 C}{3 L}\right)$, and an effective panel load, $W \left(1 - \frac{2 C}{3 L}\right)$. It is evident, however, that this last result, which has been adopted in the report, is inapplicable to the case of the panels of a slab on separate supports.

Common practice makes C not less than $0.2L$, while $C = 0.225$ is a usual value, and we have, consequently

$$0.87 > \left(1 - \frac{2 C}{3 L}\right) > 0.85 \text{ and } 0.76 > \left(1 - \frac{2 C}{3 L}\right)^2 > 0.72.$$

Hence, it appears that, by reason of the size of the capitals alone, the constant applied bending moment may possibly be reduced to

$$0.85 \frac{W L}{8}$$

independently of any other reductions that may occur, such, for example, as that treated in the previous sections. However, the amount of reduction proposed in the report, which would make the total constant applied about $0.75 \frac{W L}{8}$, or about $\frac{W L}{11}$, is evidently unwarranted by theory, even in case the circumstances were such that the span were reduced by the entire diameter of the capital, for the minimum span would then be

$$L - C = L(1 - 0.225) = 0.775 L.$$

9.—Recapitulation.—First.—The formula proposed in the report for the thickness of slabs does not conform to accepted usage in reinforced concrete design, which increases the steel ratio with increase in the ratio of thickness to span. Consequently, the formula for thickness makes the proposed minimum thickness too large for large loads and spans.

Second.—A continuous flat slab on separated supports is an indeterminate structure in which the distribution and relative intensities of the stresses depend on the relative rigidities of the parts acting, and, in particular, on the massing and location of the steel, so that the statical limitations applicable to ordinary statically determinate structures are not valid in such a slab. Mr. Eddy.

Third.—On account of the necessary sub-division of the total shear arising from the panel load which is carried in the two directions parallel to the sides independently, the total applied bending moment acting parallel to each side is only 50% of that stated in the report in case of inside panels, and 60% of it in case of outside panels, provided the latter be taken to be 20% greater than the former, as recommended in the report.

Fourth.—The recommendation that the dip of the reinforcing rods from top to bottom of slab be distributed at various distances from the edges, is not well founded. A dip common to all neighboring rods should be used to fix the position of the lines of inflection and, at the same time, to fix the sub-division of the constant total applied moment between mid-span and margins.

Fifth.—The recommendation that the cross-section of steel across panel-wide sections at mid-span and margins be apportioned in certain proportions between the inner sections and the sections at the column heads, is without basis in sound theory, and should be cancelled.

Sixth.—The coefficient of reduction of the total applied moment due to the usual diameter of capitals is approximately $\left(1 - \frac{2}{3}\frac{C}{L}\right) = 0.85$ and not $\left(1 - \frac{2}{3}\frac{C}{L}\right)^2 = 0.75$, as recommended in the report.

C. A. P. Turner,* M. Am. Soc. C. E. (by letter).—Mr. Scott analyzes the report of the Joint Committee in respect to the modulus of elasticity of steel embedded in concrete beams on the assumption that the steel furnishes the entire tensile resistance due to the moment of the applied load. This assumption is not correct. Furthermore, the assumption that the tensile strength of the concrete furnishes that portion of the tensile resistance necessary to produce a static balance of the moments not provided for by the steel is likewise incorrect. Mr. Turner.

This latter assumption, although incorrect, is found in almost every treatise on reinforced concrete published either in America or abroad. There is one treatise, however, that by Charles F. Marsh, M. Am. Soc. C. E., which shows that the distribution of stress in a reinforced beam is not analogous, or even approximately analogous, to that of a homogeneous beam in respect to any uniform distribution of intensity of the stress transversely of the beam between

* Minneapolis, Minn.

Mr. Turner.

reinforcing bars. All agree that there is a co-action between the metal and the concrete in a beam, brought about by the resistance of bond stress, which prevents the steel from slipping in the concrete matrix. Under uniform load in a simple beam, all agree that bond stress is zero at mid-span and increases toward the end of the beam. Now, this bond force or bond stress is a horizontal shearing stress along the surface of the steel. Consequently, it sets up tensions and compressions at 45° to the surface of the metal; the intensity of these indirect stresses is greatest next to the surface of the bar, and diminishes, according to the law of distribution of force through mass, with the distance away from the surface. The deformation of the concrete due to the bond is greatest near the bar, thus forming a cone of deformation about the bar, and smaller deformations or strains occur between consecutive bars in the plane of the reinforcing steel than take place at the surfaces of the bars themselves. This condition of deformation causes some of the energy of internal work to be performed at an angle to the axis of the bar, or laterally, thus differentiating the reinforced concrete beam from the beam of homogeneous material in relation to the storage of internal energy.

It cannot be maintained consistently that burying the steel in the concrete changes its molecular properties or its modulus of elasticity, because, when we dig the steel out after it has been embedded in the concrete, we find that it is just the same kind of steel as it was before it was embedded, and possesses the same properties; and any conclusion to the contrary is unwarranted. It cannot be maintained that the joint action of the combination is equivalent to the resistance furnished by a plain concrete beam without any steel whatever plus the resistance of the tensile stress in the steel multiplied by its lever arm, because experiments in which the concrete is divided or separated at mid-span of the beam by pieces of tin so that no tensile stress can be transmitted in the tensile zone from one-half of the beam to the other by the concrete, show to a large extent the same phenomena of apparent but not true increase in the modulus of elasticity of the steel when measuring its deformation at mid-span and right across the line where it is dissociated from the concrete.

The subject of horizontal shears in vertical planes is one that is little understood by the Engineering Profession, or by theoretical writers on the subject of reinforced concrete. Lack of familiarity with this kind of action has led to an erroneous report by the Joint Committee as to the strength of reinforced flat slab and column construction, and to the unwarranted assumption in the report that the tensile strength of plain concrete in the slab can account for the enormous increase in strength which it exhibits over beam action in the column-supported flat slab. Less assumption and more experi-

mental work and a careful discussion thereof would have resulted on the part of the Joint Committee in a far different report, and one which would not be questioned, as this one will be by all who have had any practical experience in the building of structures of this type. Mr. Turner.

This phenomenon of reinforced concrete is not so simple and apparent as it may now seem, even after the explanation has been discovered. It required nearly 3 years of hard study and investigation before this satisfactory explanation was obtained. This question was discussed in a paper presented to the Boston Society of Civil Engineers, in September, 1914, in which the phenomenon was compared in action to a thrust applied at the end of the beam. The law of conservation of energy applied to the problem would prevent a consideration of the tensile stress in concrete multiplied by its lever arm as balancing that portion of the applied moment not carried by the steel, because of the lateral action introduced in the cone-shaped deformation through the operation of bond stress about the bar toward the end. These internal shears seem to be somewhat equivalent in their action to the effect of a thrust applied at the end of a beam, and not greatly interfered with by cutting the concrete through the tensile zone at mid-span.

Although the operation of horizontal shears in vertical planes is not to be depended on in a beam, because the utility of this action is destroyed by the cracking of the concrete toward the end of the beam, the conditions are different in the continuous flat slab floor, where the tendency to rotate is predominantly about a vertical instead of a horizontal axis, and, for that reason, is dependable.

A further point of interest lies in the fact that although every pound of pull in the steel is brought on it by bond stress, the work of internal deformation in tension is largely stored within the steel, a conclusion which was far from being apparent in the first consideration of the subject. Static balance merely requires equal opposing forces, with no restriction as to the amount of work performed directly by these forces, so that although the steel may store very largely the internal work of tensile deformation, horizontal shears in vertical planes may have an equal effect in reducing deflection without performing the same relative amount of work, since they operate in a radically different manner and through a much shorter range of action.

The writer presented some tests at a meeting of the Concrete Institute relative to this subject several years ago, but has not been able to supplement them by further experimental work, as he had hoped to do by this time.

Mr. Scott deserves the thanks of the Profession for clearly bringing out the incongruities of the Joint Committee's theory which he notes

Mr. Turner.

and which the writer has endeavored to explain. Figs. 11 and 12 show, in an exaggerated manner, the condition discussed.

The impossibility of assigning any dependable value to the tensile strength of the concrete in a floor may be made apparent by the following experiment conducted by the writer. A slab, about 24 ft. square and 5½ in. thick, supported on the edges on beams and piers and by a center pier, was loaded as shown in Fig. 13. It carried this load, consisting of concrete barrels filled with water, without

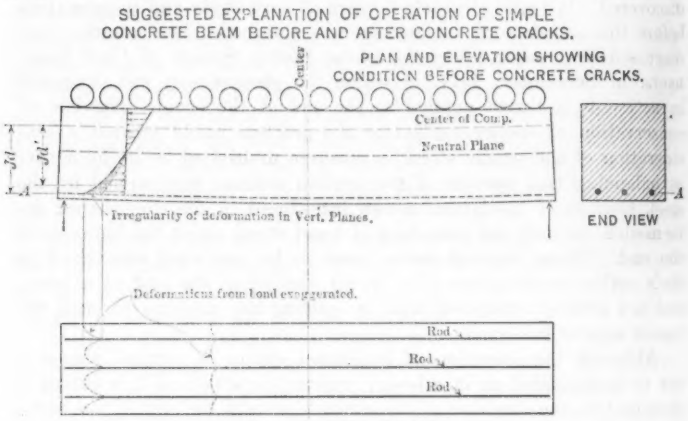

FIG. 11.

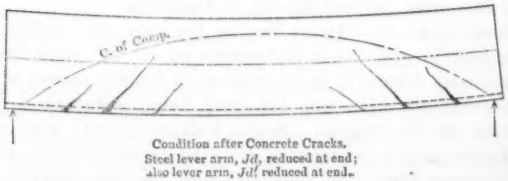

FIG. 12.

signs of failure when first applied, but a drop of temperature of about 25° caused the failure shown in Fig. 14. If a change or drop in temperature of only 25° is sufficient to overcome the tensile strength of concrete, even when assisted by a little wire netting, as was the case here, the error of relying on such resistance as furnishing any dependable load-carrying capacity in the average building, which is subjected to greater reduction of temperature than this test slab was, is apparent, and needs no further comment.

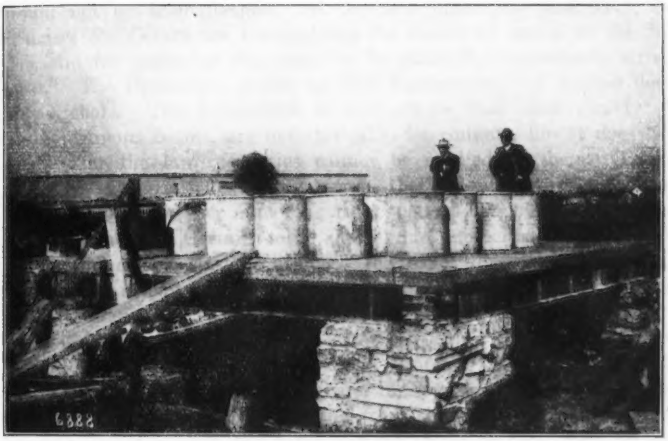

FIG. 13.—SLAB CARRYING LOAD WITHOUT DISTRESS, VERY LARGELY BY VIRTUE OF THE TENSILE STRENGTH OF THE CONCRETE.

FIG. 14.—FAILURE OF SLAB SHOWN IN FIG. 13.

Mr. Turneaure.

F. E. TURNEAURE,* M. AM. SOC. C. E. (by letter).—Professor Eddy's discussion of the report of the Joint Committee raises certain fundamental questions which should be answered. It appears to the writer that his analysis at certain points is absolutely incorrect, and should not go unchallenged. In the first place, on page 1178, he criticizes the Committee for applying the theory of statics to the flat slab, and for assuming flat slabs "to be statically determinate structures." The Committee makes no such assumption, and neither does Mr. Nichols. The Committee is well aware that such structures, like continuous beams, are not statically determinate, but it does not follow that the law of statics cannot be applied to them. To be statically indeterminate simply means that the unknown quantities in the problem are too numerous to be determined by the equations of statics alone. Certain total shears and moments, however, can be determined by statics, although the exact distribution of these shears and moments cannot be thus determined. This is the position of the Committee.

It is interesting to note that, after criticizing the Committee for applying the laws of statics to this case, Professor Eddy, on page 1179, proceeds to do the same thing, where, in Paragraph 3, he applies the laws of "equilibrium" to determine total shears—a perfectly correct procedure, and exactly the same sort of thing as that done by the Committee. The same process can be used to determine total bending moments along either axis, and it is quite unnecessary to make use of any involved mathematical process to do this. Although the total bending moments can be determined in this way, their distribution along the slab cannot, and, in this degree, the problem is statically indeterminate.

Professor Eddy finds that the total shear around the edges of a square slab is equal to the total load—a result with which the writer fully agrees—but the results obtained by his analysis for total bending moments are quite erroneous. For a square panel, he finds that the numerical sum of the positive and negative bending moments along the center line, and along one edge, is $\frac{1}{16} W l$, whereas the correct value is $\frac{1}{8} W l$ (neglecting the effect of size of column in reducing slightly the bending moment). As this question is a very fundamental one, and as the conditions of the problem may easily result in confusion in applying the ordinary laws of statics, it will not be out of place to discuss this matter on a rather elementary basis.

* Madison, Wis.

Mr. Turneaure.

Consider a square panel, Fig. 15, loaded uniformly with a total load, W. Assume that the columns are equivalent to square columns, in accordance with Professor Eddy's conclusions on pages 1179-80. For simplicity, consider that the columns are small as compared to the size of the panel, so that the size of the columns need not enter into the expression for bending moments. The total shear at the columns will be W, and the shear on each of the surfaces, AB, BC, etc., will be $\frac{1}{8}W$. There will be no shear on the lines, AG, CD, etc. These statements agree with Professor Eddy's conclusions.

Now proceed to the question of moments: Consider the half-panel to the left of the center line, JK, Fig. 16. There will be bending moments at all points of the periphery, these moments acting in a direction at right angles to JK along the surface, JK, and also along the surfaces, AB, CD, and EF. Moments along the surfaces, AJ, CB, DE, and FJ, will act in a direction parallel to the axis, JK. The load on the half-slab is $\frac{1}{2}W$ and the shears are $\frac{1}{8}W$ on each of the surfaces, AB, BC, etc. Now, taking moments about the axis, JK, the external moment is that of the couple formed by the load, $\frac{1}{2}W$, and the four shears of $\frac{1}{8}W$ each. This moment is practically equal to $\frac{1}{8}Wl$. For equilibrium, the sum of the internal moments must also equal $\frac{1}{8}Wl$, and the internal moments in question are the positive moments along JK and the negative moments along AB, CD, and EF. That is to say, the numerical sum of the negative moments along a line through the columns and the positive moment along the center is equal to $\frac{1}{8}Wl$, as given by the Committee.

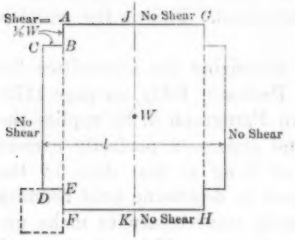

FIG. 15.

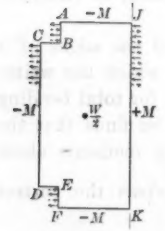

FIG. 16.

This method of analysis is a simple, direct application of the laws of equilibrium, quite as definite as the application of these laws in determining shears. No amount of mathematics will enable the conclusion to be reached that the internal moments acting perpendicular

to the surfaces, AJ, CB, etc., can help balance the bending moments about an axis, JK, at right angles thereto. Mr. Turneaure.

In contrast with this result of $\frac{1}{8} W l$, Professor Eddy arrives at $\frac{1}{16} W l$ by a process of analysis in which he omits the effect of the shears on the surfaces, CB and DE, considering that these shears affect only the bending moments parallel to JK. As a matter of fact, the shears on CB and DE are a little more effective in producing bending moments about the axis, JK, than those on AB and CF, on account of the increased lever arm. The fallacy of Professor Eddy's position may be brought out clearly by noting what happens if we consider the portion of a slab limited by the lines, AF and GH, Fig. 15. Neglecting the small load applied directly to the strip, $BCDE$, and the similar strip on the right, the total shears on the lines, AF and GH, must be equal to the load, W, by the same process of reasoning as that heretofore used. Then, if we consider one-half of this slab and take moments at right angles to the axis, JK, as before, the external moment will be plainly $\frac{1}{8} W l$, which must be equal to the total internal moments along the lines, AF and JK.

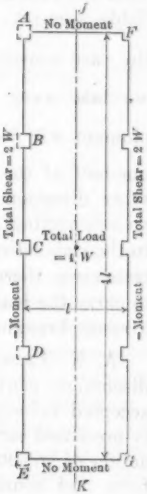

FIG. 17.

The inevitable conclusion, therefore, is that the numerical sum of the negative and positive moments along the edge and center line of a square panel is approximately $\frac{1}{8} W l$, and not $\frac{1}{16} W l$.

The matter may be clarified still further, perhaps, by considering an entire row of panels across a building. Suppose, for example, that the floor is four panels wide. In Fig. 17 is shown a row of four such panels, AF and EG being the exposed edges of the floor; AE and FG are sections through the floor. The columns are at A, B, C, D, etc. There are no bending moments on the edges, AF and EG. The total load is 4 W, and the sum of the shears at Columns A, B, C, D, and E is 2 W. The shears at the several columns are no longer exactly equal, on account of the discontinuity at A and E, but the sum is the only quantity needed. Now, take a section through JK, and consider moments on the left. The external moment is $2 W \times \frac{1}{4} l = \frac{1}{2} W l$. This is equal to the sum of the internal

Mr. Turneaure.

moments on the lines, JK and AE, acting perpendicularly to JK. The average moment per panel will be one-fourth of this, or $\frac{1}{8} W l$, as previously found. This result seems very clear, as, in this case, there are no internal moments along AF and EG to confuse the issue.

This analysis leads to the conclusion that the sum of the moments on JK and AE is precisely the same ($2Wl$), no matter what the number and spacing of the columns along AE and FG may be, as long as the arrangement is the same on each side, so that there is no shear on the line, JK. If the supports consist of continuous walls along the lines, AE and FG, the same result will be reached.

This leads to the general conclusion that, with symmetrical conditions with respect to the axis, JK, the sum of the internal moments along AE and JK is precisely the same whether the supports be walls, or columns spaced in any manner, a result which is not incompatible with the fact that the structure is statically indeterminate. Professor Eddy seems to agree that the bending moment for wall supports in the case considered would be $\frac{1}{2} W l$, but maintains, in effect, that if we take away most of the wall, leaving only small columns, the moment will be immediately reduced to $\frac{1}{4} W l$. As a result of this, one-half of the reinforcing rods may be taken out and placed in the other direction and the slab be made considerably thinner. This is an astonishing result, and obviously incorrect. The interior moments in the slab acting parallel to the axis, JK, cannot help out the moments transverse thereto. They have their own duty to perform, namely, to carry the load from column to column in the longitudinal direction, a result brought about by changing walls into columns.

Mr. Talbot.

A. N. TALBOT,* M. AM. SOC. C. E. (by letter).—Professor Eddy's discussion contains so many fallacies and so many violations of accepted principles of mechanics that it is hardly believable that it is presented seriously by one who is familiar with the analysis of the action of structural parts. Since reasoning presented in mathematical form and coming from one of high standing may appear plausible, the erroneous statements and conclusions may mislead, and a more explicit answer is needed than will seem necessary to some readers.

Professor Eddy puts forward the astonishing statement that "any assumption of the validity and applicability of statical analysis to continuous flat slabs is incorrect, and leads to erroneous results, just as much as in the case of continuous beams or of any other indeterminate structures." That statical principles are valid for all structures is generally accepted, and it is difficult to believe that Professor

* Urbana, Ill.

Mr. Talbot.

Eddy intends to deny this generally accepted truth. Static analysis does not reveal all the conditions of indeterminate structures. For example, it cannot give the distribution of the intensity of the resisting moment along sections of the flat slab. Nevertheless, the indeterminate structure must be amenable to the statical laws of forces and moments, even though Professor Eddy seeks to exempt the flat slab from such laws.

On page 1183 he gives a mathematical derivation of what he terms the total applied bending moment. In this derivation he uses the accepted relation between vertical shear and rate of change of bending moment, $dM = S_x dx$. In determining S_x, he adds the total vertical shear at a section, AB (Fig. 18), and the total vertical shear at a section, CD, and equates this sum to $\frac{Wx}{L}$ — the latter being the load between one of these sections and a middle section of the panel. It is evident that $\frac{Wx}{L}$ is the value of the total vertical shear on either one of the two sections, and not that of the sum of the total vertical shears on the two sections. He does not explain why he unites the shear of these two "free bodies" in the expression and yet considers the external load on only one. By this violent assumption, at one stroke the bending moment found in his analysis is cut in two. If the analysis was in any way defensible, the resulting moment coefficients would produce a wonderful saving in the dimensions and costs of structures. As the analysis involves a gross violation of the principles of mechanics, one must brand it as fallacious. That the sum of the numerical value of the positive moment at a mid-section and the numerical value of the negative moment at an edge-section is $\frac{1}{8} Wl$, as a limiting value for very small capitals, and not $\frac{1}{16} Wl$, as given on page 1184, rests on as firm a basis of logic as do any of the accepted expressions for bending moment in beams, girders, and other structures.

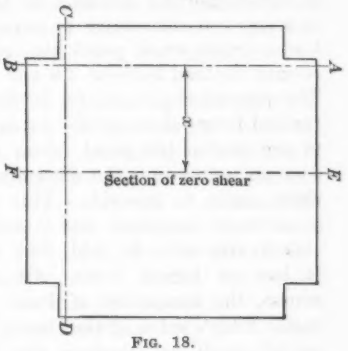

FIG. 18.

On page 1181 Professor Eddy states that the total vertical shear in sections parallel to the sides of the panels of flat slabs is 50% less than in a wide beam structure which rests on parallel walls, and

Mr. Talbot.

that the total vertical shear in a section parallel to one of the sides of a panel is only that which arises from a uniform load of $\frac{1}{2}$ W. This means that the vertical shear along a line, AB (Fig. 19), close to the supports, is only $\frac{1}{4}$ W, or less. It is plain that such a statement violates the principles of equilibrium of forces acting on the portion of the slab, $ABFE$, principles which are just as applicable with a continuous slab having sections of zero shear along boundaries, except at the supporting columns, as they would be for an isolated panel. It seems too elementary to require pointing out that, for a uniform load over the whole panel, the total vertical shear on the section, AB, is once the load between AB and CD and not one-half of that amount. The presentation made by Professor Eddy assumes that a series of vertical forces along a side of a square which lies in a direction parallel to one side of the panel (shear along one edge of a square column) does not enter into the determination of equilibrium for sections at right angles to this side. This method of cutting the shear in two is not even ingenious, and it seems hardly necessary in a discussion among engineers to add that it has no logical basis. Of course, the acceptance of Professor Eddy's value of the shear would result in dividing the moment by two.

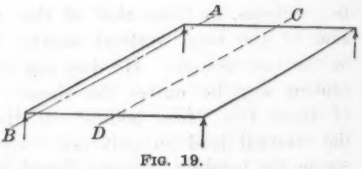

FIG. 19.

Attention may be called to the different view put forth by Professor Eddy in a paper* before the American Concrete Institute in 1916. In this paper he derives and accepts the value $\frac{1}{8}$ WL as the applied bending moment each way in a panel (the limiting value for very small capitals), instead of $\frac{1}{16}$ WL, as given in his discussion. Further on in this paper, starting with $\frac{1}{8}$ WL, he reduces the amount of moment necessarily provided for by a series of steps; (*a*) he divides it by two, because for two sets of reinforcing bars at right angles to each other, embedded in a matrix of concrete, the effect is the same as if the two sets of bars were a sheet of metal of the same weight, and hence a set of bars will have the same resisting effect laterally as longitudinally; (*b*) he divides it by two again, because as the bars do not slip in the concrete, the concrete will do as much work in a given

* "A Further Discussion of the Steel Stresses in Flat Slab Floors," *Proceedings*, Am. Concrete Inst., Vol. XII.

direction as the steel; and (*c*) he states that tests appear to show that the effect of Poisson's ratio reduces the stresses in the reinforcing bars of the slab to three-fourths of what they otherwise would be. The combined effect is to divide the moment by $5\frac{1}{3}$, and he gives $\frac{3}{128}WL$ as a final value for the sum of the positive and negative resisting moments, on which to base the design of the reinforcing bars, instead of $\frac{1}{8}WL$ before referred to. If these considerations were added to the effect of halved shear given in his discussion already referred to, the result ($\frac{3}{5\frac{1}{3}}$ of that given by static analysis) would produce moment coefficients which would effect remarkable economies in structural design. Mr. Talbot.

Professor Eddy favors bending all reinforcing bars downward at a point fixed at the same distance from the panel edge. Although the position of the point of dip may be expected to affect that of the point of inflection somewhat, the differences produced for ordinary conditions will be slight, especially as the stiffness of the concrete in compression and tension has considerable influence. The recommendation in the report provides for such changes in the position of the point of inflection as may result from a change in the distribution of the load on the floor or from its concentration, and adds to the diagonal tension resistance of the slab, as well as avoids a possible plane of cleavage.

The actual distribution of the intensities of the resisting moments along a section of the panel will be affected by variations in resisting stiffness in different parts of the panel, but, as the concrete of the slab in its compressive resistance, and to a certain extent in parts of the slab in its tensile resistance, is a great factor in making up the stiffness of the slab, changes in the location or distribution of the reinforcing bars over a panel-wide section will not affect the distribution of intensities of resisting moment to any such extent as is claimed by Professor Eddy. The report allows a considerable leeway in the manner in which the reinforcing bars may be distributed over a section. It may be added that experiments have not borne out the claim for added strength in saddle-shaped portions.

Professor Eddy objects to the recommendations made for general thickness of flat slabs on the ground that it has been indubitably established that the ratio of steel reinforcement to concrete may be made greater in beams of relatively large depth over that permitted in beams of relatively small depth. The attempt, on page 1169, to establish this statement by the relation between the sharpness of the curvature and the horizontal shearing distortions in the concrete at points distant from the sections where maximum moments occur, is

Mr. Talbot.

absurd. If true, the criticism would apply also to the principles of design of all beams and girders. Besides, the relation of thickness to length existing in the ordinary flat slab is that of relatively long beams. In establishing values for the formula for slab thickness, Professor Eddy starts with two assumed examples of thickness of slab for definite panel lengths, considered to be known from experience, and, later (page 1174), he naïvely suggests that it will be sufficient to assume that l (given as the total panel length in the derivation of formulas and Table 3) is the effective span (a dimension shorter than the panel length) and may be so regarded in using Table 3. Professor Eddy seems to have overlooked the fact, which a little study will show, that the formulas given in the report for thickness of slabs with and without dropped panels are devised to produce working stresses, in both reinforcing bars and concrete, which are in close agreement with the values of working stresses ordinarily used in design when the moments and their distribution are taken as recommended in the report.

On page 1191, Professor Eddy first uses $L - C$, and then adopts $L - \frac{2}{3} C$, as the span of the panel in determining the effect of the size of capitals. The expression for moment given in the report corresponds closely to the moment of the couple formed by the resultant of the load on the half panel and the resultant of the shears at the column supports. A more exact expression is found in the paper by John R. Nichols, Assoc. M. Am. Soc. C. E., on "Statical Limitations Upon the Steel Requirement in Reinforced Concrete Flat Slab Floors."* That given in the report is a close approximation to the more exact expression.

Any information or analysis which will furnish grounds for reducing coefficients and dimensions of engineering structures should be welcomed. To be acceptable, such grounds must stand the tests of the fundamental principles of mechanics and of the known action of structures. Doubtless, the future will see many developments in concrete and reinforced concrete. With increased knowledge and experience in construction, in the choice of materials, and in the methods of work, and with the greater confidence which may develop with continued use, it is not improbable that, in the future, it will be found proper to increase allowable working stresses to more than those now recommended, and even to encroach on the margin between allowable loading and the critical load which a structure will stand—the so-called factor of safety. Practice will change, and recommendations must be revised from time to time, but changes should not be based on misapplication of basic principles.

Paper No. 1399

FINAL REPORT OF THE SPECIAL COMMITTEE TO INVESTIGATE THE CONDITIONS OF EMPLOYMENT OF, AND COMPENSATION OF, CIVIL ENGINEERS*

WITH DISCUSSION BY MESSRS. H. S. SCHICK, LEWIS A. JONES, AND R. S. WISE.

THE AMERICAN SOCIETY OF CIVIL ENGINEERS,
220 WEST 57TH STREET, N. Y. CITY.

GENTLEMEN: The Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers submitted its second report at the Annual Meeting held on January 20th, 1915. With that report there was presented statistical information based on 4 796 replies to circulars sent out by the Committee, the information being given in diagrammatic form and covering the following:

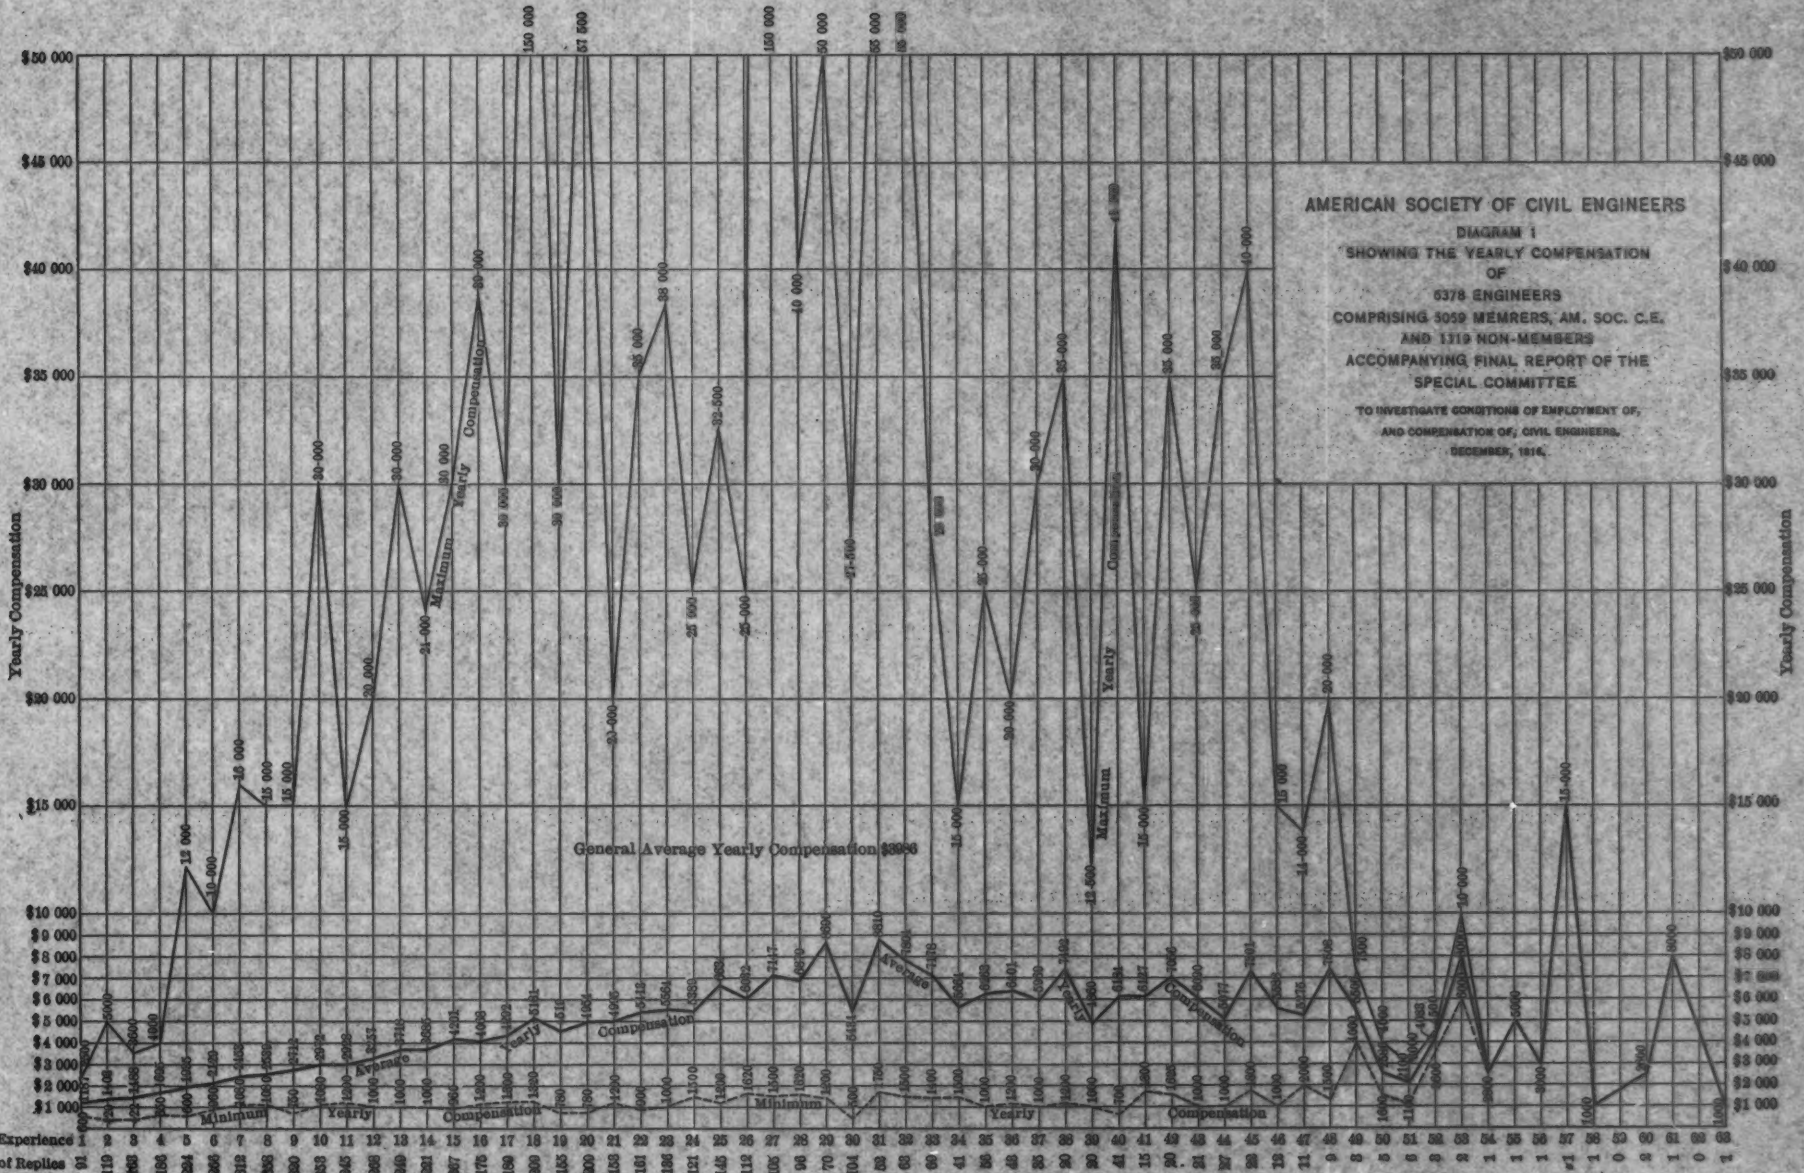
1.—Maximum, minimum, and average yearly compensation, together with that of the middle man or the man occupying a position where equal numbers of individuals receive a greater and a less annual compensation. These figures were given for every year of experience from 1 to 63 years, although the number of replies received from those who have been in active practice for more than 47 years were so few that the information with respect to them was considered of little value.

2.—The average yearly compensation according to the nature of employment, classified in eight groups, namely, States and Counties, National Governments, Municipalities, Technical Schools, Railroads, Private Companies, Consulting Engineers, and Contractors.

3.—A geographical classification arranged in six groups, namely, Southern States, Western States, New England States, Central States, Middle Atlantic States, and Foreign Countries.

* Presented to the Annual Meeting, January 17th, 1917.

4.—A classification separating graduates of technical schools from non-graduates, this being supplemented by a statement giving the relative ages of graduates and non-graduates for those whose experience covered from 2 to 15 years.



The report of the Committee was received and the Committee was continued. The Committee has endeavored to secure information concerning a larger number of engineers, and, with this in view, has extended its inquiries outside the membership of the Society. While additional requests for information were sent out and many replies were received, the Committee was unable to present a formal report at the Annual Meeting of 1916, and simply reported progress.

In accordance with the expressed wish of the Board of Direction, that the work of Special Committees be completed as soon as possible, the Committee now presents its final report.

During the summer of 1915 the Committee addressed the same questions which were addressed to those whose replies formed the basis of its last report to those who had become members of the Society since the last preceding circular was sent out, the number of inquiries so sent being 599, from which 263 replies were received. Inquiries were also addressed to 6 393 non-members of the Society, whose names were secured from the membership lists of fifteen local engineering organizations in different parts of the country, after having first eliminated from these lists all who were members of this Society. From these non-members 1 319 usable replies were received, which, together with the additional members of the Society heard from, brings the total number of returns received by the Committee to 6 378.

The Committee has considered the advisability of addressing letters of inquiry to members of the other National Engineering Societies, but has concluded that this would be inexpedient, for the reason that there are quite a number of members of these societies who are also members of the American Society of Civil Engineers, and they are probably those whose compensation or income from professional work is above the average, so that, if those who are members of this Society were excluded, the result would not indicate the average compensation of members of the other societies, and might be misleading. The Committee also made an effort to secure information from the different engineering schools, but it was found that, with two exceptions, the statistics collected by these institutions concerning their graduates, with respect to the matters which have been the subject of the Committee's investigations, were so incomplete that this idea had to be abandoned. An attempt was made to secure pertinent data from officers of railway and other corporations, municipalities, States, and Federal departments which employ large numbers of engineers, but

SPECIAL COMMITTEE TO INVESTIGATE
THE CONDITIONS OF EMPLOYMENT OF, AND
COMPENSATION OF, CIVIL ENGINEERS.

they appeared to consider it impracticable to undertake the collection of such data for the Committee, and, without their active co-operation, it has not been possible to secure any information of value.

The Committee, therefore, is obliged to base its third report on the information received from the 6 378 engineers who have replied; and that these figures are worthy of serious consideration is obvious from the fact that the 5 059 members of the Society represent a gross annual professional income of not less than $20 952 952, while the 1 319 non-members represent a gross annual income of $4 467 709, or a total for those whose replies form the basis of our report of $25 420 661.

The returns from the 263 additional members of the Society, the great majority of whom were younger men, when combined with those covered by the last report, result, as might have been expected, in lowering the average compensation from $4 224 to $4 142, or $82. The average annual compensation of the 1 319 non-members is $3 387, or $755 less than for the members of the Society, including the latest returns. The Committee realizes that in directing its inquiries to individuals outside of the membership of the Society, but members of local engineering organizations, it has addressed a number of men who are not really practising engineers, as the local engineering organizations almost always include in their membership men who may be simply interested in engineering and some who have done little, if any, professional work, and they have been frank enough to say so in their returns, and their replies are not included in our statistics.

Twenty-two of the replies indicated that the men who made them are employed as sales engineers or in other lines of commercial work, although they are graduates of engineering schools. These men appear to have turned their attention to this kind of work immediately after graduation. The Committee has not included these returns in its compilation, but they are so significant as to be deemed worthy of comment. They include men whose active work covers periods of from 1 to 22 years, although in all but four instances their experience in work of this character has been 10 years or less. A comparison of their earning power with that of men engaged in what is generally considered to be strictly engineering work indicates that it agrees very closely with the averages shown by the diagrams, even though the responsibilities which must be assumed are less than those of the practising engineer.

The Committee submits herewith five diagrams as follows:

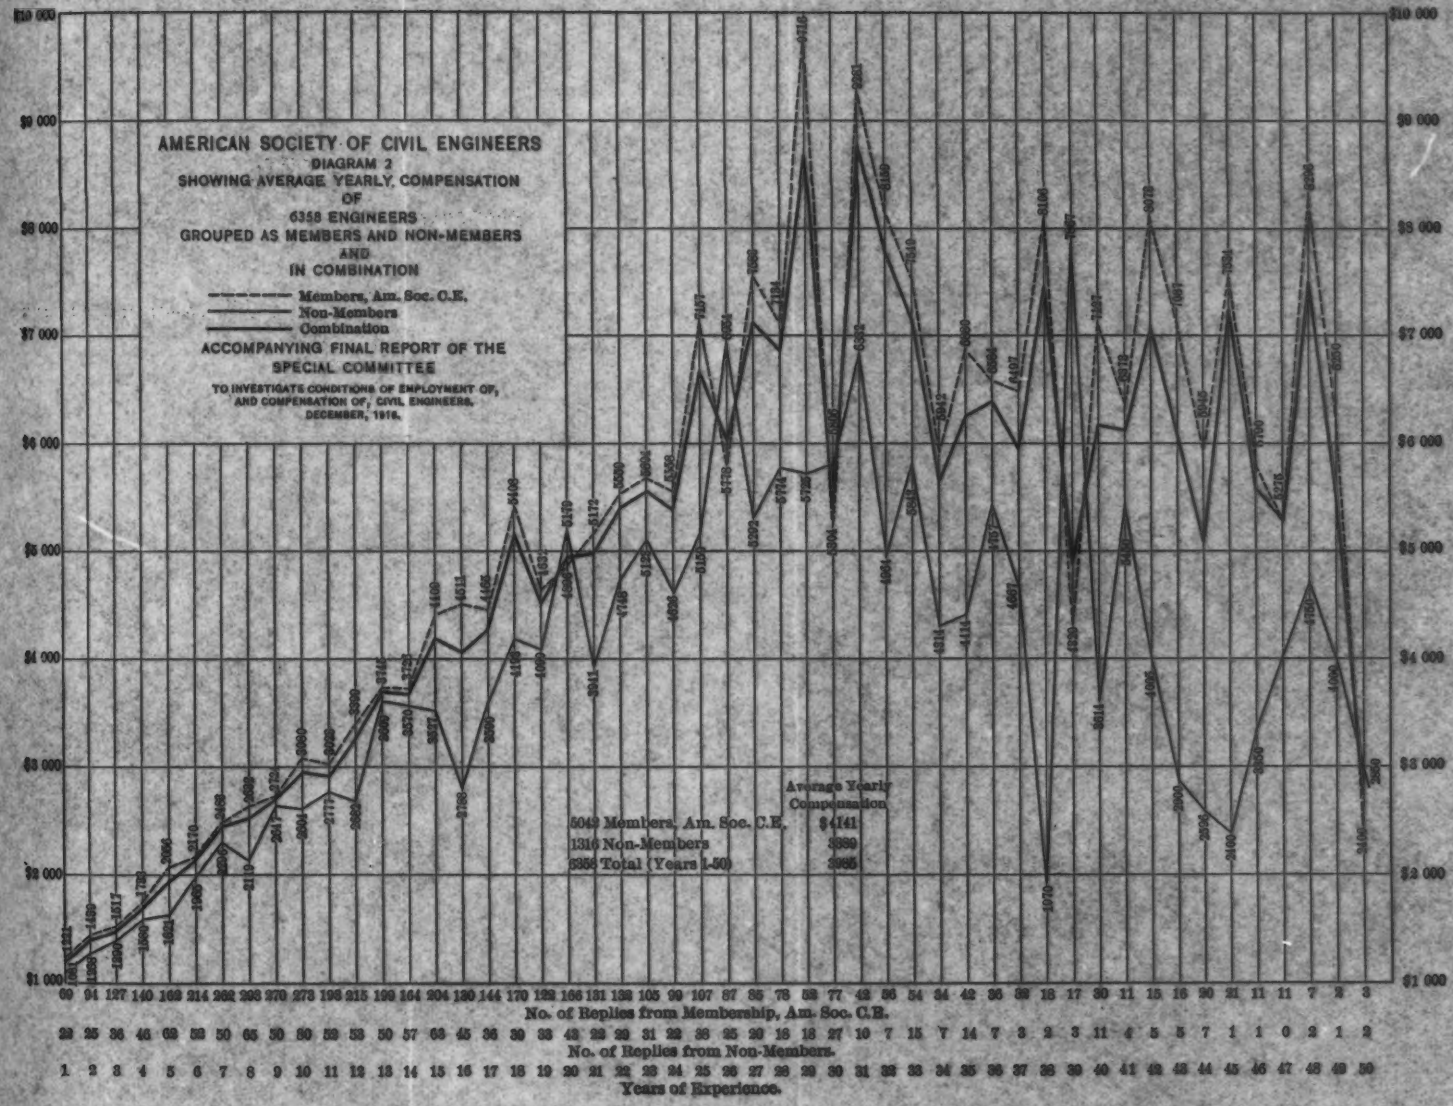
1.—A diagram similar to that reproduced as Plate XL* in the last report, showing maximum and minimum average annual compensation for professional work of 6 378 engineers, including 1 319 who are not members of the Society.

* *Proceedings*, Am. Soc. C. E., for December, 1914.

2.—A diagram showing the average yearly compensation of 6 358 engineers, divided into members of the Society and non-members, together with the combined average.

3.—A diagram showing the average compensation of graduates and non-graduates, arranged according to 5-year periods.

4.—A diagram showing the average compensation of engineers grouped according to nature of service.



5.—A diagram showing the average compensation of engineers arranged in six geographical groups.

The first of the above diagrams includes all the returns which have been received. The second and third include all returns covering professional activity of 50 years or less, while the other two cover all those which are capable of being classified with certainty and which include 40 years or less of professional work.

Your Committee has considered the question as to whether exceptionally large professional incomes, say those above $25 000 a year, might not be due to some fortuitous circumstance or condition entirely apart from professional ability, and whether they should not be excluded from consideration in the preparation of the diagrams by arbitrarily reducing them to $25 000. This was tried and, while the effect was to modify very materially the curve showing maximum professional incomes, its effect on the curve of average compensation was very slight. The Committee believes that the data collected include practically all the very large professional incomes, and that an increase in the number of returns would tend to eliminate the irregularities of the curve. The Committee's conclusion has been that the returns should be shown as they were received.

A comparison of the diagrams with those presented with the last report will show that the broader scope of the Committee's inquiry has not produced any substantial changes in the results heretofore submitted. The line indicating the average compensation of non-graduate engineers falls below that showing the compensation of graduates, except during the first part of the first 5-year period, where the professional earnings of non-graduates appear to be slightly greater than those of graduates. The Committee has communicated with bodies which are collecting data concerning professional education, in the hope that it might secure information relative to the compensation of men engaged in other kinds of professional work. Its inquiries have not produced any definite results, and, so far as the Committee can learn, no data as complete as are herewith presented have been secured with respect to them. From such meager information as was obtainable, the Committee is convinced that the compensation for engineering work compares favorably with that received by men of any other profession. Engineers, like other professional

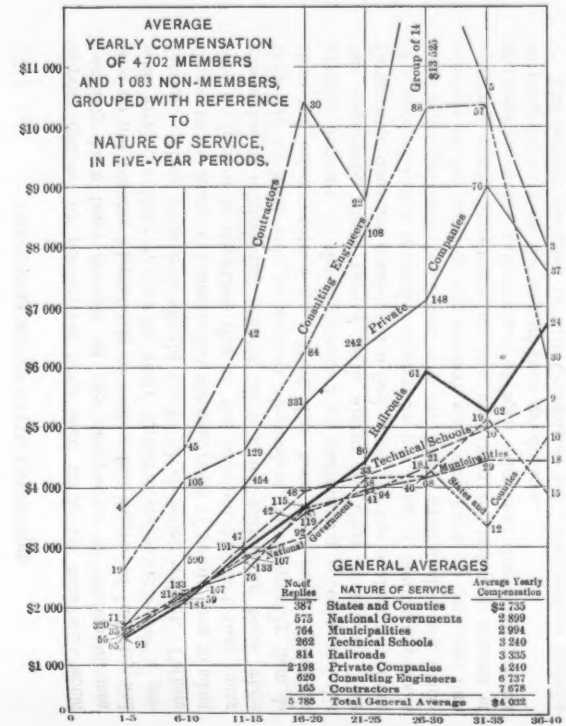
Years of Experience, in Five-Year Periods

DIAGRAM 3.



or business men, are frequently desirous of being connected with important undertakings which will give them valuable experience and a certain prestige, and, in order to gain these, they are willing to accept salaries which are very small in comparison with the value of the services rendered.

The underpaid engineer does not always owe his failure to receive a salary commensurate with the importance or difficulty of his work to the ignorance or lack of appreciation of laymen, but it not infrequently is the fault of his engineering superior in the organization of which he is a part. The replies received by the Committee indicate that engineers in private practice sometimes employ men of extensive experience, and presumably of good ability, at salaries which young graduates with little or no experience are able to command, but which are less than those of an ordinary mechanic who has a labor organization behind him. It may be urged that the competition for work on the part of engineers who employ a technical staff is so keen that it is necessary to take advantage of the needs of those seeking employment in order to secure professional work which is frequently let to the lowest bidder. Engineers in private practice are often criticized because they have not established a scale of charges on a percentage basis as have the architects, but in the offices of leading architects will be found young men who are willing to work for almost nothing for the sake of the experience they hope to gain. The fact remains that employing engineers are sometimes disposed to pay their men less than their services are actually worth. The Code of Ethics, adopted by the Society by letter-ballot on September 2d, 1914, lays special emphasis upon the relation of the engineer to his client and to that of competing engineers, who may be striving to secure the same contract or commission, toward each other, but it makes no mention of the obligations of the engineer as an employer to men of his own profession. It appears to lose sight of the need of guarding against underpaying as well as against underbidding.

The engineer, in some branches, unlike other professional men, is frequently unable to locate in one place until he can become known, even though his reputation may be local. He must go where work is in progress, and, when the particular work on which he has been engaged shall have been completed, he must move on to another place. Periods of unemployment are fatal to steady advancement, while a reasonable prospect of promotion, however slow, is likely to prompt men to accept less than the average compensation for the kind of service rendered.

In reading the observations made by those who have commented upon the compensation of engineers and the conditions of their employment, it has appeared to your Committee that many of those which

appear cynical or pessimistic have been made by men who would probably have been failures in any occupation or profession, men who do not possess adaptability or even a fair degree of industry, and who attribute their failure to their unfortunate selection of a profession. These comments should not be given much weight. Perhaps there are too many engineers, but the eagerness of young men to adopt this profession is doubtless due to the indisputable fact that young graduates of engineering schools reach a self-sustaining basis, where they are at least able to support themselves, more quickly than do those of other professions. Much has been said lately about the general decrease in the registration at engineering schools, and this has apparently been viewed with alarm by their faculties. Your Committee does not consider it a bad omen for the profession. There is a need of better trained engineers rather than of more engineers, a need more particularly of men who are better grounded in the fundamentals of the engineering sciences and who have at the same time acquired some knowledge of the economic or business aspects of engineering work, rather than of men who may have the greatest earning capacity on the day of their graduation.

The subject assigned to this Committee for investigation includes not only the compensation, but "the conditions of employment" of engineers. The information collected and herewith presented may be thought to relate only to compensation and not to conditions of employment, except to the extent that the latter may be the cause of, or may result from, the former. Judging from the replies received by the Committee and the extended comments accompanying some of them, conditions of employment are believed to be capable of expression chiefly, if not wholly, in terms of compensation. The Committee has repeatedly discussed the meaning of "conditions of employment" and what was the probable intent of the Society in the inclusion of these words in the title of the Committee. To give it the broadest interpretation to which it is susceptible and to follow the lead indicated by such interpretation would have led the Committee into a more or less controversial discussion of social conditions, and might have resulted in a report of greater length, but of no more value. That there lately has been a more general appreciation of the importance and dignity of the Engineering Profession cannot be denied, and the part which engineers are now taking, on the invitation of the Federal Government, in the investigation of the resources of this country and their prompt and effective utilization for national defense or in any other crisis, together with the more cordial co-operation between men in different branches of the Engineering Profession, will do much to increase further this estimate of the value of engineering service.

The Committee wishes to express its grateful appreciation of the co-operation which it has received from members of the Society and others, and for the valuable advice and assistance extended to it by the Secretary of the Society and members of his staff. It asks that this be accepted as its final report, and that it be discharged.

Respectfully submitted,

NELSON P. LEWIS,
Chairman.

COMMITTEE:

JOHN A. BENSEL,
S. L. F. DEYO,
DUGALD C. JACKSON,
WILLIAM V. JUDSON,
NELSON P. LEWIS,
C. F. LOWETH,
GEORGE W. TILLSON.

NOVEMBER 15TH, 1916.

DISCUSSION

Mr. Schick.

H. S. SCHICK,* ASSOC. M. AM. SOC. C. E. (by letter).—This Committee has performed a valuable service in a matter which is of first importance in the work of the Society. The diagrams accompanying the report are interesting, and their scope and limitations have been fully discussed by the Committee.

An important principle brought out in the report should receive further attention, for the purpose of emphasizing the helpfulness of the Society in promoting effectually the feeling of reciprocal usefulness, the spirit of co-operation between members, and, at the same time, perform a service of especially practical value to the profession.

The writer refers to the principle that the compensation of every engineer, aside from his return on physical capital invested, depends entirely on his own efficiency—both his technical and his selling efficiency. All know, on the one hand, as stated clearly by the Committee, that engineers frequently receive a lower compensation than their services should demand, and, on the other hand, that the search for the proper man to perform a given service is always attended with some difficulty and much loss of time. This difficulty may be charged to the fact that, in marketing their services, engineers are not always good salesmen, and have not the most ready means to acquire reliable disinterested information regarding the demand for their work. For a number of years, the American Society of Mechanical Engineers has maintained a bureau for the purpose of gathering and publishing, in several ways, just such data for the use of its members, at a cost which is surprisingly low, and with highly gratifying results.

This matter is brought to the attention of the members of this Society, now, for the purpose of eliciting discussion, and perhaps ultimately turning the valuable contribution of this Committee toward the accomplishment of a practical end which will be of much satisfaction to all.

Mr. Jones.

LEWIS A. JONES,† ASSOC. M. AM. SOC. C. E. (by letter).—There is one point in this report to which the writer desires to call attention. In Diagram 4, giving the average yearly compensation grouped with reference to nature of service, the curve for employees of the National Government is shown to increase in a fairly regular manner, with an average yearly compensation of $2 899. Attention is called to the fact that no distinction is made between army and navy engineer officers and civilian employees. It is a well-known fact that engineer officers in the Government service receive practically twice as much as civilian employees, counting the allowances for quarters, etc., and, as a result,

* Wheeling, W. Va.
† Montgomery, Ala.

the curve, in its present shape, does the civilian employees an injustice. Could not a separate curve be made for each? The writer believes that the results would show the engineer officers' curve following closely the curve labeled "Private Companies", and that for the civilian engineers well below the one labeled "States and Counties". Mr. Jones.

R. S. WISE,* ASSOC. M. AM. SOC. C. E. (by letter).—This report is very complete and interesting, so far as it relates to the civil engineer, and the Committee deserves a great deal of credit for its work. Mr. Wise.

The writer is sure that a great many of our members would like to see a committee appointed to investigate and find ways and means of regulating the fees which the municipal engineer and surveyor should get for his services. As it is now, there is no schedule of fees on which such a man may base his charges.

On account of keen competition, he must base his charges on local rates, which in most cases have been established for many years; but, if rates were established, clients would not go shopping to see which surveyor would do his work the cheapest.

There should be fixed rates for establishing grades, cross-sections, and calculations of quantities on street work, for giving lines and grades for curbing, guttering, flagging, macadamizing, etc. Minimum rates for staking out lots, based on the size of the lot, for surveying and mapping out land, based on the location; one rate for the fire or congested district and another for the rural section.

There should be some understanding as to Court charges, not strictly for professional work, but for the surveyor's knowledge as to certain lines, maps, etc. In the district around Passaic, N. J., it has been the habit of some lawyers to employ the surveyor to locate certain properties, and later to subpœna him, often keeping him in Court two or three days, breaking up his field party, and not paying him for his time in Court.

Paper No. 1400

FINAL REPORT OF THE SPECIAL COMMITTEE ON FLOODS AND FLOOD PREVENTION*

WITH DISCUSSION BY MESSRS. H. M. EAKIN, JOHN W. HILL, M. O. LEIGHTON, CYRUS C. BABB, KENNETH C. GRANT, B. F. GROAT, H. M. CHITTENDEN, MYRON L. FULLER, GERARD H. MATTHES, H. K. BARROWS, N. C. GROVER, E. C. LA RUE, FARLEY GANNETT, C. E. GRUNSKY, C. MCD. TOWNSEND, AND MORRIS KNOWLES.

General.—With the growth of the United States, the question of flood control is daily assuming greater importance, but as yet has not received the attention which it merits. When a country is a wilderness, a flood occasions little damage, and is rarely recorded, but as the valleys are cleared and the farmer attempts to utilize them, the injurious effects of floods begin to be felt. With the growth of cities and villages, there arises a still greater demand for protection against overflow. While there is no conclusive evidence that great floods have increased in frequency or volume in recent years, with the growth and development of the country, the damage which is caused has been greatly intensified, and the obstruction of the flood plain by the works of man has in many cases largely increased flood heights for the same volume of discharge.

It is only in recent years that the property losses during floods have been reported, but these are rapidly increasing and becoming a serious burden on the resources of the country. Nor are they confined to any particular section. Floods of great intensity are liable to occur in semi-arid regions where the mean annual rainfall is less than 20 in., though possibly with less frequency than in regions having an average rainfall of over 60 in.; and a mountain stream with a slope of 6 ft. to the mile, is as liable to overflow its banks as

* Presented to the Annual Meeting, January 19th, 1916.

an alluvial river with a slope of 6 in. per mile. In fact, the greatest loss of life from floods usually occurs on the minor streams, whose waters rise with great rapidity and flow with great velocity.

Data Deficient.—On most streams the physical data collected have been for other purposes than flood control, and are therefore deficient in the specific information necessary for such an investigation. In a river which is being improved for navigation, the essential element requiring consideration is the low-water flow.

When a stream is to be utilized for water-power, again the first consideration is the low-water flow. If it is proposed to increase the low-water discharge by means of reservoirs, the engineer is interested in average conditions, and if he discusses those of extreme floods, it is only to provide a sufficient capacity for flood discharge without danger. Similarly, in determining the water-supply for a city, it is the low and mean flow of the stream which receives special consideration.

In discussing flood control, low and average conditions are of little value. A great flood is caused by an exceptional combination of most adverse conditions. A mean rain falling on a soil having a mean percolation and mean run-off, with a mean evaporation and other average conditions, produces about a mid-stage flow in a river. The extreme flood stage occurs when a maximum precipitation falls on a soil which because of frost or previous saturation has a minimum percolation and a maximum run-off, with a minimum evaporation. Such combinations are comparatively rare, and unless some one is specially delegated to investigate them, generally escape observation.

It is not only the causes of extreme flood discharge, however, on which additional data and further study are required. There is a large field for investigation in the influence of the works of man on the regimen of streams, and in the evaluation of all the little-understood factors that determine the flood height obtained from any given discharge.

Suggested Methods.—The methods of flood control which have been suggested may be summarized as follows:

(*a*) Methods of reducing extreme variations in rainfall and increasing the soil absorption of water, so as to diminish the run-off; reforestation, soil drainage, variations in methods of plowing, the construction of small dikes in agricultural areas, which will retain on the soil a large portion of the rainfall until there is time to absorb it.

(*b*) Reservoir and detention basins which will retain the crests of the run-off and discharge them at lower stages.

(*c*) Barriers thrown across mountain streams to prevent erosion and the transportation of débris.

(*d*) Channel improvement, cut-offs, and the construction of auxiliary channels.

(*e*) Levees which will confine the flood waters to the channel.

(*f*) Outlets for the purpose of facilitating the discharge of the streams.

Present Knowledge.—There is nothing to indicate that man can modify either the intensity or distribution of precipitation. To utilize the forces of Nature, which will reduce the effects of excessive precipitation or increase the absorptive power of soils, necessitates an intimate knowledge of the intensity and distribution of the rainfall over the drainage area to be considered, of the character of its vegetation, of the permeability and depth of the overlying soil, and of the capacity of subterranean fissures and conduits to carry off the water which may penetrate to the underlying formations—subjects on which but a limited amount of information is at present available to the engineer.

The Weather Bureau has established stations for observing the precipitation, and the results are published in its monthly bulletins. Most of these observations, however, extend over a relatively short period of time, and it is improbable that the maximum precipitation that may occur at a given locality has yet been recorded. Moreover, they are generally taken in cities on high buildings where the gauges are not protected from wind, or in villages located in the valleys, and the relation of the precipitation over a built-up territory to that of the surrounding country and upon the uplands and divides has not been well determined.

The series of studies made by the United States Geological Survey on the surface water supply of the United States are necessarily based on comparatively few observations frequently taken at less than flood stages. With such an extensive field to cover, the observers cannot wait for extreme conditions on each stream, but must pass from stream to stream measuring the discharge which happens to exist when the observer is present. In 1914 the Geological Survey made stream-flow measurements at 3 400 points and maintained 1 480 gauges in conjunction with co-operating parties; many more are needed.

Care must be exercised in the use of discharge curves or rating tables. They may represent only average conditions, and when applied to a particular case may lead to large errors. Their extension above a bank-full stage cannot be depended upon for accurate results. With sedimentary streams in particular, both the slope and the area of cross-section are subject to abrupt changes, and floating débris may land against a pier or otherwise obstruct the flow in such a manner as to entirely change the relations which exist at lower stages.

At every town subject to overflow from a neighboring stream, there is urgent need of co-operation, not only to extend the discharge

curves to extreme stages, but also to investigate the variations which may occur. On rivers which are being improved for navigation, such co-operation may be afforded by those engaged in the work of river improvement, and even though not strictly required for the development of a navigable channel, should, if necessary, receive Congressional authorization. On other streams, State commissions and private agencies are at present collecting data, all of which should be co-ordinated, studied, and published by some National agency.

But in considering flood control, the amount and character of the sediment carried is next in importance to the discharge of the stream. The advisability of reservoir and barrier construction, the practicability of enlarging the stream section, of affording relief by auxiliary channels, and of levee control, will be influenced by this factor. In streams carrying a large amount of sediment, the checking of the normal velocity by reservoir construction will cause its deposit; a sudden enlargement of the section of a stream will similarly reduce velocities and cause deposits, and this deposit is liable to occur during low stages, filling the channel on which reliance is placed for relief from flood discharge. If an auxiliary channel is built, a difference in velocity in the two channels is accompanied by a tendency of one or both to fill.

An extensive series of observations on the flow of sediment in the Mississippi and Missouri Rivers has been made by officers of the Corps of Engineers, U. S. Army, and the Mississippi River Commission, from 1879 to 1884. The Geological Survey has also published, in Water Supply Papers 236 and 274, investigations of the flow of sediment in other rivers.

Similar data on many other streams requiring flood control are lacking, and should be supplied.

A knowledge of the topography of the country, which is essential before plans for flood control can be formulated, is also lacking. In the Thirty-Fourth Annual Report of the Geological Survey it is stated that about 38.9% of the United States had been surveyed, and these surveys are generally plotted on maps of a scale of 1:62 500 and 1:125 000 (about 1 in. to 1 and 2 miles, respectively) with contours 20 and 50 ft. apart. Such surveying and mapping, even in greater detail, should be prosecuted with vigor and co-operative action by the General Government and the various States until the entire country has been covered.

For the large rivers the present maps give but few contours at wide intervals in the valleys, and the usefulness of such data in a study of flood control is therefore limited to purposes of reconnaissance. With the exception of those of the Mississippi, Missouri, and Illinois Rivers, the surveys for the improvement of navigation have been generally confined to the river bed.

The organic act creating the Mississippi River Commission stipulated among other duties that such surveys, examinations, and investigations of the Mississippi River and its tributaries should be made as might be deemed necessary for the purpose of formulating plans for the prevention of destructive floods. As a result of this legislation the Mississippi River Commission has been engaged for the last 35 years in collecting data relating to the flood control of the Mississippi River. An accurate hydrographic survey has been made of the river from its head-waters to its mouth, with a topographical survey covering practically the entire width of the valley down to the head of the alluvial basin near the mouth of the Ohio, and extending to a distance of about 1 mile upon either side, with occasional sections across the entire alluvial valley, below the Ohio. Maps have been prepared on a scale of 1:10 000 with contours 5 ft. apart. Discharge stations have been established on the main river and also on some of the larger tributaries where the flow is not affected by back-water, and the discharge curves have been developed from a long series of observations. In the earlier stages of the work, daily observations of sediment and discharge were made at several stations for periods of over a year. In later years, discharge measurements have been confined to prescribed stages above the normal high water and below the average low water, in order to trace any changes in regimen that might occur. Numerous gauge stations have also been established on the main river and its principal tributaries where the height of the river is recorded at least daily, and observations have been made to determine the slope, at both high and low water, and other hydraulic factors.

By the River and Harbor Act of June 18th, 1880, a project was adopted for the construction of forty-one reservoirs in Minnesota and Wisconsin to collect the surplus water from the precipitation of winter, spring, and early summer, and release it during low water so as to benefit navigation on the Mississippi River. In 1887 the scope of the project was reduced to include reservoirs at the head-waters of the rivers in Minnesota, only, and there have been constructed six reservoirs with a capacity of about 96 000 000 000 cu. ft. and having a drainage area of 4 535 sq. miles.

These reservoirs, while built for the low-water regulation of the river, were much larger than any others that had then been built by man for the high- or low-water control of rivers.* Careful records have been kept of the rainfall, the contents, and discharge of these reservoirs since their construction; and they afford most valuable data as to the flood control of a river by reservoirs, particularly as there is a

* Three basins on the Ottawa River now under construction will have a capacity of 168 000 000 000 cu. ft.

different relation for each reservoir between its capacity and the area of its water-shed.

The surveys and estimates for reservoirs in Wisconsin, under the original project, afford further data for the discussion of flood control of the tributaries of the Mississippi River in that State.

The California Débris Commission has carried on a series of investigations of the Sacramento River and its tributaries, which are useful in determining the flood control of that drainage area. Important studies on the Allegheny and Monongahela drainage area have been made by the Pittsburgh Flood Commission. A large amount of data on the Miami River has been accumulated, in connection with the work of the Dayton Flood Prevention Committee. The Scioto River has been made the subject of an extensive study at Columbus. And several flood commissions have been appointed by Governmental agencies, such as the Ohio River Flood Board of the U. S. Army Engineers and the Commission of the States of Indiana and Pennsylvania, though few of these have yet had sufficient opportunity to contribute any extensive studies upon stream regulation. Some of the minor valleys have been surveyed by cities to determine the proper source of a water supply, and a few corporations have determined the capacity of certain streams to develop water power; but, on the whole, there is a great dearth of reliable data as to rainfall, run-off, and other physical facts needed by the engineer for the proper solution of the problem of flood control, and the accumulation of the proper data will require many years of careful observation. Even with proper data available, the determination of the method of flood control, which is to be applied to a particular case, will require careful consideration and the greatest exercise of engineering skill. No method can be devised that will be susceptible of universal application.

Discussion of Suggested Methods.

(*a*) *Reforestation.*—If reforestation is considered merely from a commercial standpoint, the value to the country of reproducing our timber is so great that it obtains general approval, particularly of engineers who appreciate more than any other class the disadvantages to which the country will be subjected by the destruction of its forests.

But some advocates of reforestation have claimed that the destruction of our forests has increased the height and frequency of floods and diminished the discharge during low water, and have based their claim for reforestation on the beneficial influence of forests in preventing floods and improving the navigation of our rivers.

The relation of forest to stream flow has been extensively discussed in this country, in papers of recent date, by the U. S. Geological Survey; U. S. Weather Bureau; Flood Board of U. S. Engineers, on the Ohio River; Pittsburgh Flood Commission; Norton, on the Rivers

of Michigan; Chittenden, before the American Society of Civil Engineers; Moore; Burr, on Merrimac River; Mead, on Rivers of Wisconsin; and the Second Report of the National Commission for the Conservation of the Waters of the United States; and others. In Europe, in addition to the classic papers of Gustave Wex, in 1873 and 1879, Keller, Lauda, and Oppokow have recently discussed conditions in Germany, Austria, and Russia, and a paper by G. Fantoli, 1913, sums up the status in the valley of the Po. An interesting discussion of the subject will also be found in the *Proceedings* of the International Navigation Congress in Milan, 1905.

In these discussions the greatest diversity of opinion has been expressed, and even the advocates of reforestation as a means of flood control fail to give any quantitative determination of the effects of forests upon floods. For the engineer to utilize any agency practically, he must know that it will produce a positive effect on which he can rely and which he can measure. The data as to the effect of forestation, soil absorption, and kindred methods of flood control are not at present susceptible of quantitative analysis.

Over a large portion of the United States freezing occurs during winter, and a heavy precipitation may occur when the ground is covered with an impenetrable layer of ice and much of the vegetation has shed its leaves. Such conditions prevent the utilization of forestation or ground storage. This was the principal cause of the great flood of 1912 which devastated the Ohio and Mississippi Valleys.

(*b*) *Reservoirs.*—The equalizing effect of lake storage on the discharge of the St. Lawrence and Oswego Rivers is frequently quoted as illustrating efficient flood control by reservoirs. But in these cases Nature has been much more lavish in the expenditure of its resources than man can afford to be. About one-third of the water-shed of the Great Lakes is devoted to reservoir purposes.

The permanent overflowing of land which can be devoted to agriculture is costly, and reservoir construction is most economical when confined to mountainous valleys where the area of tillable land is small when compared with the volume of water that can be stored. On many streams this condition materially limits the applicability of reservoirs as a means of flood control, particularly in thickly settled districts.

It also frequently happens that a reservoir can be more profitably utilized for other purposes, such as power development, irrigation, or the water supply of a city. There is a popular delusion that the same reservoir can be utilized simultaneously to reduce floods, increase the low-water discharge of a stream, and increase the water-power that can be developed therefrom, but ordinarily its utilization for any one of these purposes precludes its efficient use for either of the others. If a reservoir is to be utilized to diminish floods, it is essential that

it be empty when a heavy rain occurs. If to increase the low-water discharge of a river, it must be full when the rainy season ceases. To insure the first condition, it is necessary to empty the reservoir after every storm, to obtain space to store the discharge of the one following. To insure the second, it is necessary to close the outlets of the reservoir at relatively low stages, and when it is once filled, not permit the surplus water to escape until the river falls to the stage when the stored water is required for navigation. Both of these processes interfere with the development of water-power, whose effectiveness is measured by the minimum discharge permitted. The cause of the trouble is the irregularity of rainfall in different years, and the necessity of being prepared for a minimum rainfall when considering navigation interests and a maximum for controlling flood conditions. In years of average rainfall, it may be practicable to utilize a reservoir for different purposes, but it is reiterated that average conditions do not enter into the problem of flood control.

Your Committee, however, does not intend to condemn *in toto* the utilization of reservoirs for more than one purpose. In fact, it believes that the practical solution of the flood problem in some valleys will be found in permitting corporations to build reservoirs in which a portion of the stored water can be utilized to a limited extent for power purposes and the remainder for flood prevention, but in such cases one of the conditions of the franchise must be the construction of reservoirs far in excess of the dimensions required for the development of the proposed power, and a rigid supervision must be exercised by the authority granting the franchise, not only to see that its requirements are fulfilled in construction, but also in operation.

There are in some localities opportunities for arresting the flow of a stream during the progress of a flood by temporary storage which limits the river discharge to that which may be safely confined within banks. This can be done by detention basins which differ from storage reservoirs in that they do not require the abandonment of the sites occupied for storage purposes. Flood control in such cases is only necessary during exceptional rains, and the basin itself may therefore be devoted to its normal uses most of the time, and only an easement on the lands occupied is necessary.

By this means cities can be protected at a minimum inconvenience to the rural community. The use of detention basins has been adopted by the Miami Conservancy District for the purpose of controlling the floods of the Miami Basin.

(*c*) *Barriers.*—Barriers erected across the valleys of tributary streams have been utilized to retain detritus and prevent its deposition in the main river. When conditions are favorable, this is a practical method of control.

(*d*) *Channel Enlargement and Cut-Offs.*—A stream flowing in an alluvial valley adjusts its channel to its discharge; when the discharge increases, the area of its cross-section is increased, and when the discharge diminishes the area of cross-section is reduced. In a river like the Missouri or the Colorado, carrying a large amount of sediment, these changes are rapid.

Where a channel is enlarged for the purpose of carrying extreme floods, it should be so designed as to give a velocity at all stages, which will prevent deposits. If not so designed, the periodic removal of deposits by mechanical means will be necessary.

A cut-off or straightening of an alluvial channel affects its slope which the stream attempts to regain, producing excessive caving of banks. Both stream-enlargement and cut-offs, while reducing flood heights immediately above them, increase the discharge capacity locally and increase flood heights below them. In alluvial rivers such work may seriously affect the regimen of the low-water channel, producing shoals, both above and below them, and should not be attempted when questions of navigation are involved or bank erosion may seriously affect other interests.

In streams of stable banks, and beds carrying but little sediment, such straightening may not be injurious.

(*e*) *Levees.*—Every alluvial stream flowing in a valley which has been formed by its own deposits, builds up its banks to a certain height which is generally known as the bank-full stage. Below that stage the stream flows in a more or less clearly defined trough and, at higher stages, it spreads over the alluvial valley. When an unleveed river rises above the bank-full stage there is an abrupt change in its regimen. The area of its cross-section increases very rapidly and ceasing to follow the sinuosities which its low-water channel has created, its currents tend to flow across points, materially changing the slope. These changes in regimen affect the movement of sediment, causing deposits at some localities and scour at others.

When the river is leveed this abrupt change in regimen is prevented to a greater or less extent, dependent on the characteristics of the river and the distance of the levee from the river bank. The function of a levee, as far as river hydraulics are concerned, is to extend the natural banks up to extreme flood stages and thus continue or possibly intensify the conditions which exist at a bank-full stage, *i. e.*, wherever a stream tends to scour or fill at a bank-full stage, that tendency may be somewhat intensified at extreme flood stages if the stream be controlled by levees which have been properly located with reference to its banks.

There is another feature in connection with levees which it is believed has been generally overlooked, and that is the increase

of channel storage which they create, and the resultant reduction of flood height from this cause. Under present conditions of levee alignment, between the mouths of the Ohio and Red Rivers, the Mississippi River has a storage capacity of 1 365 000 000 000 cu. ft. (about 30 000 000 acre-ft.).* When we consider this enormous reservoir effect, it is evident that flood control on the Mississippi River below the Ohio cannot be realized without the use of adequate levees.

(*f*) *Outlets.*—Outlets are at best of doubtful utility in reducing the flood heights of sedimentary streams, even where additional lines of flow to the sea or lake into which the stream empties are practicable. The frictional resistance of the river bed limits their influence to a comparatively short distance above them. In a delta formation they usually require leveeing to protect the adjacent country from overflow and in a river carrying a high percentage of sediment, either the outlet or the main stream will diminish its area of cross-section by fill and thus reduce the discharge capacity and ultimately defeat the purpose for which the outlet is constructed.

Three natural outlets from the Mississippi River to the Gulf of Mexico may be cited as illustrating this principle. The Atchafalaya River leaves the Mississippi at a point about 200 miles above New Orleans and reaches tide-water at a distance of 100 miles from its source, while the main river traverses a distance of 300 miles before reaching the Gulf. Although having three times the slope of the main river, the entrance to this outlet practically closed itself at low stages by natural processes of deposit and, in order to maintain navigable depths, annual dredging has become necessary, and if this were suspended the closure would doubtless in time become effective.

The Jump, an outlet which leaves the right bank of the river about 10 miles above the Head of the Passes, was once a formidable outlet, but is now of insignificant proportions; Cubits Gap on the left bank, about 5 miles above the Head of the Passes, which was cut through to the Gulf in 1862, at first enlarged very rapidly to a width of over ½ mile with a maximum depth of 80 ft. near the entrance, but has now become a shallow outlet which is being rapidly obliterated by deposits.

So far as the Mississippi River is concerned, whose regimen has been closely studied for over half a century, the observed effects of the natural outlets that have been described and the effects of crevasses in levees carrying one-fourth of the flood volume of the river with but a small reduction in gauge heights, all point to the conclusion that the use of outlets in any form for the purpose of reducing flood heights will generally fail to secure the desired results.

* The Roosevelt Dam in Arizona stores about 1 500 000 acre-ft.

Conclusions.

Your Committee therefore submits the following conclusions:

Reforestation.—The effects of forest growth in preventing erosion on hillsides are sufficient to justify reforestation for that purpose, but there has been no quantitative determination of its influence on stream flow which would justify its employment as a method of flood prevention.

Reservoirs and Detention Basins.—At the head-waters of streams, storage reservoirs and detention basins can be successfully employed to reduce flood heights. Which method is preferable is dependent on local conditions. Their efficiency, however, rapidly diminishes as the distance from them increases.

Cut-Offs, Channel Enlargement, By-Pass, and Outlets.—In clear-water streams, whose banks and beds are not subject to scour, these agencies may be profitably employed. In streams carrying a large amount of sediment, whose banks are readily eroded, great care should be exercised in their employment, always bearing in mind the fact that the best conditions on an alluvial stream follow its confinement to a single channel.

Levees.—As you proceed down stream the influence of reservoirs on flood prevention rapidly diminishes, and the influence of levees correspondingly increases in importance as a method of flood protection. On the lower alluvial reaches of long rivers, such as the Mississippi and Colorado, they afford the only sure means of flood control.

Your Committee believes that it can perform no greater service to the Profession than to call attention to the paucity of the data existing in reference to flood control and to the damage which may result from river regulation legislation, either by the Nation or the States, calling for definite projects which are not predicated on full and thorough investigation.

While valuable results have been obtained by National departments and bureaus and State and local commissions, with the limited means at their disposal, such investigations have generally been subordinated to other questions than flood control, and there is pressing need of intensive study directed especially to this end. Moreover, these agencies have worked on independent lines, and there has not been the necessary co-ordination of their observations. Progress would be much more rapid if each local investigation could be brought to follow some uniform method of procedure and to cover all of the points included in a standard outline, which would permit the fullest utilization of the data obtained.

Your Committee desires to urge the great importance of the early establishment and unification of systematic rainfall, run-off, and flood observations, covering the entire country in far greater detail than has yet been attempted.

While the co-operation of all agencies engaged in river regulation is desirable, the question of flood control is becoming of such vital importance to the country that it should not be subordinated to questions of navigation or power development. The disasters of 1913 in the Ohio Valley—involving a property loss of $67 000 000, and more than 361 lives—and that at Kansas City, in 1903—involving a property damage of at least $10 000 000—occurred on non-navigable streams, and on some of the navigable rivers the interests affected by floods are of far greater importance than those connected with navigation. If considered merely as an accessory to navigation, the limits of investigation of flood problems will be vastly curtailed, and their usefulness correspondingly diminished.

The members of your Committee have received reports from many sources covering investigations in connection with stream flow, and have been much gratified with the prompt, cordial responses to inquiries for data. In digesting this information it soon became apparent that reliable records of past floods were too meager and covered too brief a period to justify at this time a general report on the floods of the country.

A voluminous report might be prepared by compiling and tabulating areas of drainage basins, slopes of streams, gauge readings, oscillations in stage, and other physical data which the Committee has gathered. But this did not seem to be judicious, since only a small portion of our members are interested in such information and those who are would doubtless prefer to go to the official records for the more complete data required in their special work. Moreover, the expense and labor involved in preparing and printing such data would be disproportionate to the value of the results.

*Endorsement of the Committee Report by C. E. Grunsky.

In concurring with the conclusions of the Committee on Floods and Flood Prevention, the undersigned desires to emphasize the fact that he is in favor of cut-offs and the straightening of river channels whenever conditions permit. The cut-off is not undesirable, as might be inferred from the language of the report, but desirable, and yet there

will be cases where bank protection may be too expensive to justify recourse to the use of cut-offs that might otherwise be thought advisable.

He desires, too, to add that, after the flood flow has been reduced by all practicable means, the aim should be:

a.—To make the stream carry as much of the flood flow as can be carried between levees of reasonable height.

b.—To allow water in excess of the maximum stream capacity to escape from the river under control at selected points.

c.—To convey the water which is allowed to escape from a river during flood stages, to a re-entry into the river or to a suitable place of outfall, under such control as will prevent undue inundation.

C. E. GRUNSKY.

MINORITY REPORT.

BY MORRIS KNOWLES, M. AM. SOC. C. E.

The writer regrets that at the last moment he finds himself in a position which requires that he submit a minority report. His disappointment is especially keen, as he was and is in substantial agreement with the report as originally drafted by the sub-committee. It is only because some portions of the report now presented represent so wide a departure therefrom and because of failure to secure such reconsideration of these changes by a reconvened committee meeting that he feels it incumbent upon himself to present these views for the consideration of the Society.

His objections to the report as now submitted relate to some expressions scattered through the paper, in which only a single view is presented on controversial subjects on which it must be recognized that much more information can and should be obtained. Such expressions, he believes, promote controversy rather than helpful discussion, and discourage rather than encourage further investigation. It would be far better to express—as is so ably done by our Board of Direction when submitting questions for vote—the reasons for and against various opinions. It is unwise to assume that we have at any time obtained all the knowledge possible upon a given subject. If we will approach the question from this point of view and with full confidence that the truth in the end must prevail, the opinions of the Society, when finally expressed, will deserve and receive recognition as authoritative.

For these reasons, therefore, the writer presents these amendments for consideration by the Society:

(1).—Page 1221, the third paragraph reads as follows:

> "Similar data on many other streams requiring flood control are lacking, and should be supplied."

In order that it may not appear that the kind of observations already made are entirely sufficient, which is probably not the case, and as there are several other items of data required for a complete study, the writer suggests that the following paragraph be substituted for that above quoted:

> "Extensive studies are needed regarding the physical and physiographic laws affecting stream loads, rates of transportation and deposition, and the variation of these factors with different conditions."

(2).—Page 1224, the first sentence, first paragraph, reads as follows:

> "In these discussions the greatest diversity of opinion has been expressed, and even the advocates of reforestation as a means of flood control fail to give any quantitative determination of the effects of forests upon floods."

This is one of the most controversial subjects upon which engineering and scientific minds have been recently engaged, and inductive reasoning does not at present result in conclusive proof in all cases upon either side of the dispute. The writer, therefore, suggests the following sentence as a substitute for that above quoted:

> "In these discussions the greatest diversity of opinion has been expressed and neither the advocates nor the opponents of reforestation as a means of flood control have completely established to universal satisfaction a quantitative determination of the effect of forests upon floods."

(3).—Page 1224, the third sentence, first paragraph, reads as follows:

> "The data as to the effect of forestation, soil absorption, and kindred methods of flood control are not at present susceptible of quantitative analysis."

Indicating our desire, as previously stated, to stimulate further research, the writer suggests the following substitute for the above quoted sentence:

> "Intensive study as to the effect of reforestation, soil absorption, and kindred methods of flood control is needed before quantitative analysis will be possible."

(4).—Page 1224, the second sentence, second paragraph, referring to frozen ground, reads as follows:

> "Such conditions prevent the utilization of forestation or ground storage."

As such conditions prevent such utilization at such times and such places, only, a more accurate statement is in the language recommended to be substituted for the above, *viz.*:

> "These conditions prevent at such times the utilization of reforestation or ground storage."

(5).—Page 1224, the second sentence, last paragraph, reads as follows:

> "There is a popular delusion that the same reservoir can be utilized simultaneously to reduce floods, increase the low-water discharge of a stream, and increase the water-power that can be developed therefrom, but ordinarily its utilization for any one of these purposes precludes its efficient use for either of the others."

As this indicates the kind of indirect adverse criticism which does not tell the whole story, the following is recommended as a substitute:

> "However, the same reservoir capacity cannot be used simultaneously to reduce floods, increase the low-water discharge of the stream, and increase the water-power that can be developed therefrom, but ordinarily, unless there be excess capacity, the use of the reservoir for any one of these purposes precludes its complete use for others."

(6).—The remainder of the paragraph just referred to comprises an entirely unnecessary and unfair discussion, purporting to show that reservoirs cannot be made useful for flood prevention, together with other purposes; whereas we know, on the contrary, that, notwithstanding all these statements, it is possible to operate reservoirs with several purposes in view, and that this is actually done in some of the great reservoir systems of Europe and America without conflict of interests. The following two sentences are recommended as a substitute:

> "It is evident, however, that such reduced efficiency for a combination of purposes does have some value, and the maximum efficiency for each purpose can be obtained by increasing the capacity sufficiently. The problem is an economic one, and much information regarding flood frequency, flood damage, reservoir operation, and comparative values of the several uses of storage is necessary before it can be satisfactorily solved in any case."

(7).—It is recommended that the first sentence in the first paragraph on page 1225, reading as follows, be omitted:

> "Your Committee, however, does not intend to condemn *in toto* the utilization of reservoirs for more than one purpose. In fact, it believes that"—

Such "damning with faint praise" is entirely unnecessary, and if such condemnation is not intended, it will be evident from the expressions, without saying so. The paragraph may well be introduced with the second sentence by omitting the first five words.

(8).—Page 1225, the third sentence, second paragraph, referring to the use of detention basins, reads as follows:

> "Flood control in such cases is only necessary during exceptional rains, and the basin itself may therefore be devoted to its normal uses most of the time, and only an easement on the lands occupied is necessary."

While it is understood that some agricultural pursuits can be carried on within and under the flow line of such detention basins, the use and occupancy of buildings, especially within their lower depth, likely to be filled to some extent each spring, cannot be permitted. Therefore the following is recommended as a more accurate statement, and as a substitute for the above quotation:

> "Complete utilization of the basin for such flood control is only necessary during exceptional rains and the land of the basin itself may therefore be devoted to its normal agricultural use most of the time and only the easement is necessary."

(9).—Page 1225, paragraph entitled (*c*): This seems to be a rather indefinite statement regarding barriers, and the following is recommended as a substitute:

> "Barriers erected across the valleys of tributary streams have been utilized to retain detritus and prevent its deposition in the main river. This has been found to be a suitable method in certain sections of our western country, where the wash of large amounts of material into the streams had disturbed the equilibrium and regimen. It is also used in Western Europe. Where conditions are favorable, this is a practical method of control, and its use will depend upon the slope of the stream and the character of the sediment being transported."

(10).—Page 1226, the last paragraph discusses the subject of increase of channel storage between levees. The writer believes that such storage is ineffective, in view of the fact that the potential storage over the surrounding country and overflowed lands is much greater than the volume confined between the levees. Therefore, considering any point on a stream below the length included within levees, the flood height is increased and not decreased by the introduction of the levees above. The writer, therefore, recommends that this paragraph be omitted.

(11).—For reasons which are apparent in the discussion hereinbefore given, the writer suggests that the four conclusions on page 1228 be amended to read as follows:

> "*Reforestation.*—The effects of forest growth in preventing erosion on hillsides are sufficient to justify reforestation for that purpose, but there has not been sufficient quantitative determination of its influence on stream flow which would justify a universal conclusion as to its employment as a method of flood control.
>
> "*Reservoirs and Detention Basins.*—At the head-waters of streams, storage reservoirs and detention basins can be successfully employed to reduce flood height. Local conditions will determine which method is preferable. The efficiency, however, of such agencies diminishes as the distance from them increases.
>
> "*Channel Enlargement, Cut-Offs, and Outlets.*—In clear-water streams, whose banks and beds are not subject to scour,

these agencies are useful. In streams carrying a large amount of sediment, whose banks are readily eroded, great care should be exercised in their employment, always bearing in mind the fact that on an alluvial stream best conditions follow its confinement to a single channel.

"*Levees.*—The influence of levees as a method of flood control becomes of prime importance on the lower alluvial reaches of long rivers and, upon certain streams, may afford the only method of flood control."

(12).—It is of little avail to submit such conclusions and recommendations without a suggestion as to some definite agency to carry on such work. Such constructive criticism will be helpful and should be presented. The writer therefore suggests the omission of the last paragraph on page 1228 and the substitution of the following, which should probably occur at the conclusion of the entire report.

"This subject is one of national importance, and while the work of State and local agencies should not be minimized, the necessity for the early establishment and unification, under National control, of systematic rainfall, run-off, and flood observations in greater detail than at present should be emphasized. Such authority should also suggest uniform methods of observation, co-ordinate information obtained, and preferably should have these duties as its main purpose, even though construction of important works for realization of results may be carried on at the same time by other agencies.

"The Committee desires to urge the great importance of the early establishment of such special agency, supported by adequate appropriations, for the purpose of studying stream regulation in its largest sense, and under whose direction all data shall be collated, according to uniform standards and systems, so that appropriate development of the science shall be made."

DISCUSSION

Mr. Eakin.

H. M. EAKIN,* ESQ. (by letter).—The Report of the Special Committee on Floods and Flood Prevention is a distinct disappointment to one interested in the general progress of applied science, who had expected the deliberations of the Committee to result in a constructive policy which would be clear of the inconclusive controversy that has heretofore hindered adequate progress in river improvement, and would, therefore, merit the endorsement of the Society and gain an effectively general support. Essentially, the report is an endorsement of specific projects of river improvement which are the subject of disagreement among scientists and engineers of standing. It also carries implications and statements that are not entirely sound.

The general spirit of the report implies that there exists an adequate, esoteric if not general, understanding of the scientific principles involved in river treatment, and that there is consequently only the need for such investigations as will furnish additional and standardized data as to the environment of their operation. The Committee evaluates with implied authority the relative merits of the various suggested methods of control, and shows its allegiance to current projects in statements that are not supported by fundamental scientific analysis.

The value of this implied authority may be indicated somewhat by an examination of the last paragraph under (*e*), pages 1226 and 1227. It is indirectly stated that the use of levees effects an increased channel storage that induces a lowering of flood levels. This is clearly impossible, since the channel storage given by levees is largely in space above the level which the same flood waters would assume if allowed to spread unhindered over the flood plain. Moreover, the confinement of floods between levees increases the facility of flow, so that discharge to successive reaches is progressively augmented above the normal as the effects of elimination of normal flood plain storage accumulate, and flood heights are correspondingly above the normal all the way to the sea. The increased flood height in the improved reach lowers the surface gradient for some distance up stream, decreasing velocities, and correspondingly increasing flood heights. The statement that levees reduce flood heights by increasing channel storage is obviously fallacious, yet it is advanced in the report as an important principle, generally overlooked, but fortunately recognized by the Committee.

The report fails of a much needed mission in not presenting clearly the present status of the science of streams. It does not indicate the scientific uncertainty as to the laws that underlie the basic problems of stream control, the reciprocal variability of discharge, grade, competence, capacity, load, torsional flow, the development, migration,

* Washington, D. C.

Mr. Eakin.

and elimination of meanders, drainage distances, assortment of débris and extra-channel deposition—in short, the reciprocally determinative relation of erosional processes and physiographic forms, and the possibilities of selective artificial mutation and control of all these factors.

The problems of stream control reach out into many different branches of science—geology, physiography, meteorology, hydrology, agriculture, forestry, and engineering—and involve abstruse laws outside the scope of these special branches, and as yet imperfectly developed or only vaguely indicated. No individual or organization has as yet commanded such proficiency in all these sciences as to enable them to outline a programme of river treatment with dependable authority. Programmes such as have been outlined from the standpoint of a single science or profession have uniformly failed to withstand scientific scrutiny from other viewpoints. The result has been controversy, partisanship, and effectual inhibition of adequate progress toward the goal at which all honestly are aiming.

Progress of applied science demands, first of all, a dependable scientific authority. As regards stream control, we are apparently without such a basis. The Society probably could perform no greater service to the Profession and to the cause of river improvement and flood control than to devise a means of supplying this lack. The obvious recommendation is that a special organization be created with a personnel made up of variously trained scientists and engineers capable of assembling the pertinent matter of other sciences and of developing by appropriate researches an adequate, specific science of streams. The sound development of the science is prerequisite to its application. Only some such means as suggested can lift the matter of river improvement above the field of speculation and controversy, and make any considerable advance toward adequate achievement.

Mr. Hill.

JOHN W. HILL,* M. AM. SOC. C. E. (by letter).—The frequency of disastrous floods in the Central and Western States during the past 12 or 13 years has directed serious attention to a condition affecting life and property which can no longer be tolerated. The periodical floods in the Mississippi and some other navigable rivers can usually be forecast as to time and river stage, and preparations can be made to discount more or less the resulting property damage; these floods or river rises are seldom attended by loss of life. There is no human foresight, however, which can predict the time of floods in the smaller non-navigable streams of the Middle West and western parts of the country, and it is with these that we are at present most concerned.

* Cincinnati, Ohio.

Floods in the large rivers of the Mississippi Basin are expected every year, although these are not always attended by great property loss or serious interference with business or transportation. Of course, there are no known means of preventing such floods. Rain and snow are bound to fall on the water-sheds, and the waters must flow away through the streams to the great reservoir in the ocean, to be caught up again into the clouds by evaporation, to make more rain and snow at a later date, and repeat the operation of precipitation, run-off, and stream flow, with frequent floods in the larger streams. Mr. Hill.

Measures to mitigate the destructive influence of great floods in the Mississippi River have been inaugurated and maintained by the States subject to damage, and by the Federal Government, Federal aid being given in the interest of navigation only.

A discussion of floods in the larger navigable rivers would have little bearing on the problem of flood prevention in the valleys of the smaller streams, and, in view of the appalling losses of life and property which have occurred from these in Ohio, Indiana, Kansas, California, and some other Central and Western States in recent years, the people directly affected by the floods have been compelled to insist on a remedy for an intolerable condition. One remedy would be to remove all habitations and perishable property permanently above the flood-plain; but this is not to be thought of as long as other avenues of escape from flood calamities are open. The vested interests in public and private property now lying below the flood-plain represent hundreds of millions of dollars in the States mentioned, and these must be preserved and protected, if individual property rights in these river valleys are to survive.

The frequency of destructive floods in the valleys of the smaller rivers and streams is often under-rated. Thus, in the Great Miami Valley in Ohio, instead of two or three great floods occurring within a century (a statement frequently made), at least five such floods have occurred within 110 years, namely in 1805, 1847, 1866, 1898, and 1913, the first and last dates marking the greatest floods.

Three of these floods have occurred within the writer's recollection. In 1866, while living in Dayton, Ohio, he saw the Miami River out of its banks and flowing several feet deep through the principal streets of that city. Marks made after the flood of 1913 indicated that, on Ludlow Street, south of Fifth Street, the flood of 1913 was about 5 or 6 ft. higher than that of 1866. In 1866, however, the city was much more open—with respect to bridges, buildings, and other obstructions—to the flow of water in the river channel and through the town, and the flood discharge for 1913 was not as much greater than that for 1866 as might be inferred from the difference in flood heights.

In 1866, Dayton had a population of 30 000, and had much unoccupied territory which is now solidly built up; no pretentious structures

Mr. Hill.

had then been erected anywhere within the city limits; the river banks were not lined with dwellings or other buildings; and, when the river rose above the levees, the water found a reasonably unobstructed channel on the lowlands behind the levees on both sides of the river.

Prior to the flood of 1913, the river banks had been pre-empted and built on up to the levees, with a street or boulevard between; several reinforced concrete arch bridges with restricted waterways had been erected in the river channel, and, in many ways, the free flow of an overcharged river had been so much obstructed that the flood discharge of 1866 would have produced higher levels in the city streets had it occurred in 1913.

The flood of March, 1805, is well recorded for the locality of Hamilton, 35 miles from the mouth of the Miami River, by a local historian,* and this flood, in that early day, with no bridges across the river, an unobstructed channel, and few improvements of any kind on the river banks, reached a height as great as that of 1913. It is probable that the dense growth of timber and shrubbery along the river banks and on the bottom lands had some influence in impeding the free flow of the river and raising flood levels; and the existing "standing timber", or forests, may have had some further influence in retarding the run-off toward the stream. If these two conditions are supposed to have balanced, then it would seem that the run-off and stream discharge of the flood of 1805 may have been even larger in the vicinity of Hamilton than in the flood of 1913.

The recurrence of great floods in all streams can be surely expected, and the subject of the report of the Committee is the remedies to be sought to prevent future disasters from this source of danger.

The writer is in accord with the views expressed by Col. Townsend in a paper† read at St. Louis, Mo., in April, 1913, on the limited effect of storage reservoirs at head-waters on floods in the Ohio and Mississippi Rivers at Cairo, owing to the relatively small drainage area which such reservoirs can successfully control; and, as has often been stated, if such reservoirs should happen to be full, coincident with a great rainfall and run-off—which is a reasonable supposition during the latter part of the winter—it is difficult to conceive that they have any beneficial influence on the stream flow below, with the whole of the run-off from the controlled water-shed flowing over the spillways and into the discharge channels below the dams. The storage of great volumes of water from the higher portions of a water-shed simply for flood control can scarcely be looked on with favor. The use of the stored water for power, for regulation of stream flow, for irrigation, or for public or industrial water supply, would be sought and probably obtained after the construction of the reservoirs, if

* Mr. James T. McBride, 1831.

† "Flood Control of the Mississippi River," National Drainage Congress.

it had not been made a feature of the original enterprise. Unless the reservoirs were kept empty before a period of great or long-continued precipitation on the water-shed, they would fail to conserve and restrain the run-off for which they were planned; and, if kept empty in anticipation of heavy downpours, they would be useless for any other purpose than flood control. Mr. Hill.

The method pursued in Europe—to allow a certain depth at the top of the reservoir for flood control—is practicable, but, in all such instances, the water stored below the flood-plain is applied to some utilitarian purpose—water supply, power, etc. The writer does not recall any investigations showing the control of flood flow below the reservoirs accomplished by this method.

The considerable number of great reservoirs in Germany and France (as far as the writer is aware) have not been constructed only to prevent floods; they have been created for other and more sordid objects. Neither have any of the great reservoirs in India and the United States been built with flood control as the only object in view.

Concerning the influence of forests and reforestation on run-off and stream flow, during periods of heavy or continuous precipitation, the flood of March, 1805, in the Miami River, at Hamilton, is probably as great as any on record for that stream. At that date, the Miami Valley was largely a wilderness, with "standing timber" everywhere on the drainage area, except in the small clearings of the pioneers, and, therefore, one of two propositions must be accepted: either the rainfall exceeded that recorded for March 23d to 26th, 1913, or the forests had small or no retarding effect on the run-off.

No record of the rainfall for the 1805 flood is obtainable, and probably there was none, but the time of year and the height of the flood suggest conditions similar to those of March, 1913, when the rain fell continuously for 4 days, the ground and all vegetation was saturated, and a time was reached during the storm when the water was flowing off the water-shed at the same rate as it was falling from the clouds; and if, in 1805, the snow and ice were added to the precipitation, probably the run-off was greater than the rainfall.

The lack of rainfall records and data as to snow and ice conditions makes it impossible to analyze the 1805 flood; but, if the virgin forests did at that time retard the run-off and restrain the stream flow, then the rainfall was probably greater than any on record on this water-shed, and it is reasonable to suppose that it will be repeated in the future. No bridges spanned the Miami in 1805, nor were there any other artificial obstructions in the channel. River crossings were made at fords, by boats, or by swimming, according to the necessities and convenience of the pioneers.

The forests doubtless have some retarding effect on run-off, up to the point of saturation of the trees, undergrowth, and shrubbery,

Mr. Hill. and of the litter and humus on the forest floor. After this point has been reached, the soil in the forest is like that in the clearings, and, as all great floods follow long-continued or very heavy downpours, it would seem that, during the storm, the time must arrive when the retarding effect of the forest is nil.

In Ohio, Indiana, and Illinois there is very little "standing timber", the water-sheds of the streams are denuded, and, after saturation of the ground, the rainfall and run-off should be nearly, if not quite, equal. The retarding influence of ponds and pools on uneven ground, formed during storms, should not be neglected, but their effect on run-off and stream flow, after all, will be small.

The proposition of reforestation with a view to flood control in the large navigable streams may be practicable for the bare lands of the West, large areas of which are not under cultivation but are used only for grazing purposes; but it will be impracticable for the valuable agricultural lands in the valleys of rivers in the Central States. It is scarcely conceivable that a farmer will give up his land to reforestation for flood control, waiting 40 to 50 years until the growing timber on it becomes valuable, and meanwhile deriving very little or no return from the land; nor is it likely that any conservancy district could afford to purchase such lands and reforest them for this purpose. In any event, it is obvious that it would be many years before such reforesting could have much influence on the rate of run-off to the streams.

The writer agrees with Mr. Grunsky that cut-offs are sometimes advantageous, perhaps not in soil like that of the Mississippi channel below Cairo; but, when made in glacial drift formation, experience has shown that they will wear and accomplish good results in flood discharge. Assuming the natural materials of the river channel to be suitable for the maintenance of permanent cut-offs, there can be no doubt that, in a certain instance, where a river, along its meanders from its mouth to its head-waters, is now 170 miles long, and can be shortened by cut-offs to 130 miles, that, with the new slope and increased velocity, the flood-plain will be materially lowered everywhere in its length.

Where the bends of a river embrace a populous city, a cut-off would be prohibitive by reason of cost, and perhaps for other reasons, but through farm lands and outside built-up city limits, it can be adopted with advantage. Where the dredged material can be used in levees, the cost of cut-offs will not be prohibitive. Some cut-offs may require training walls, or spur dams, in order to maintain the alignment of the channel, and the materials for these can often be found on the ground.

With the materials before it from which to draw, it is to be regretted that the method of "flood prevention" by so-called "detention" or "dry" reservoirs has not been more fully developed. The literature

available to the writer shows few of such reservoirs, and none quite recent in date of construction, if the work now under way on the water-shed of the Little River in the southeastern part of Missouri, and a few reservoirs in prospect,* may be excepted. Mr. Hill.

Suppose a water-shed, having 75% of its area embraced in the drainage area of the small tributaries, generally of steeper slope than the rivers they feed, with channels often narrow and comparatively deep, often with rocky beds and conditions generally favoring the easy construction of check dams or barriers, and where the valley next to the river, as a rule, is wide and flat, and thoroughly developed, with many populous and prosperous cities and towns along the stream, the river very crooked, with the channel running through a drift formation ranging from builders' sand to large boulders, where cut-offs can frequently be made to straighten and shorten the channel, the stability of cut-offs and diversion channels in this instance having been proved by a test of more than 60 years: Is not this an instance where the retardation of flow—or, if desired, storage of water for flood protection—should be in the narrow valleys and ravines of the smaller tributaries, rather than in the main valley; and is not this also an instance where channel improvement will apply?

M. O. Leighton,† M. Am. Soc. C. E. (by letter).—The writer's impression, gained by reading this report, may be expressed substantially as follows: Here is a Committee of eminently qualified engineers —unquestionably as well qualified as could be selected from the Engineering Profession. To this Committee has been assigned one of the most important and difficult subjects in the engineering field. As the members of the Committee are eminent engineers, it follows naturally that they are very busy men. They realize, more acutely than any reader of their report can, that they have not had the time to give their subject the attention that it deserves. Having accepted appointment to this Committee, they do not wish to shirk the service involved. Therefore, they have made a safe and conservative report which, in all probability, each member regards as inadequate. Mr. Leighton.

Perhaps the writer's impressions are wrong, but, having had the benefit of acquaintance with some of the members of the Committee, and having, during past years, become familiar with the reputation and accomplishments of the others, he cannot avoid the conviction that this report on floods and flood prevention falls considerably short of the standards to which the Committee members have previously adhered. Such a result is not unprecedented in the lives of busy and well-qualified men.

The subject of floods and flood prevention is each year occupying more of the time and attention of National legislators. Among these

* Briefly mentioned in Appendix 5, of the "Report of the Pittsburgh Flood Commission".

† Washington, D. C.

Mr. Leighton.

legislators, doubt and diversity of opinion seem to be growing apace. One who has followed the events in Congress for the past ten years, and who has therefore acquired a mental picture of the legislative situation, must realize that the subject has not progressed to that point of finality with respect to fundamental facts and remedial measures which will insure a comprehensive legislative solution. The flood question crops out in debate on measures both relevant and irrelevant. The same old truths and the same old fallacies are printed each year in the *Congressional Record*. With admirable persistence, Senator Newlands of Nevada presents a great and comprehensive proposal that involves every feature of correction and improvement either closely or remotely related to stream flow and stream utilization. With equal admirable persistence, other Members of Congress advocate divers measures. The House of Representatives has recently created a new standing committee on floods and flood prevention, and it remains to be seen what the practical results of this new move will be. In connection with all this, two truths stand out prominently: First, that the Members of Congress who are expected to legislate wisely in this matter, and who, almost without exception, have no engineering qualifications, have the right to expect from the foremost civil engineering society of the country a definite and meritorious expression of opinion that will, in the end, define that which should be done. Second, it is the patriotic duty of every engineer, and certainly of this great National Society of Civil Engineers, to satisfy the reasonable expectations of the legislators.

It does not benefit any legislator to tell him about fundamental principles or to give him a summary of the things which cannot or which should not be done. The legislator is looking for a concrete proposal that will stand the test of analysis. A legislator who may be utterly incapable of formulating a proposal may be quite successful in analyzing, criticising, and pointing out, the weak spots in a proposal submitted to him by qualified engineers. Let us not deceive ourselves about this matter. If the flood problem is to receive final and successful legislative treatment, it will be only after the engineers of the country have come forward with a definite legislative measure, based on physical facts and well-attested engineering principles. This statement may do violence to the sacred tenets of the American Society of Civil Engineers. The writer can already hear the deprecatory expressions of many members with respect to the Society's participation in legislative matters and advocacy of any particular proposal. There is no doubt that such an attitude is comfortable, dignified, and utterly safe, but the fact remains that, if the Society expects to see the consummation of a successful solution of this problem, it must do the useful and necessary thing, rather than the dignified and comfortable one.

Mr. Leighton.

There is no trade or profession in the United States in which one may find such persistent and general expressions of discontent over the inadequacy of legislation as in the Engineering Profession. It is also fair to say that, in the opinion of the writer, there is no profession in which such expressions are so intelligently and considerately given. On the other hand, it is the writer's observation that there is no class of complaining citizens which so consistently fails to come to the aid of legislators with definite concrete advice. If the members of the Society dissent from this statement, let them ask the legislators.

From the foregoing, it will be seen that the writer criticises the Flood Committee's report because it leaves the country and the country's legislators precisely where they were before the Committee undertook its labors. If a traveler who has lost his bearings and has become confused amid a maze of divergent paths, asks the route to his destination, he is not benefited by a reply which says in effect: "Friend, you must take the proper road that leads to your destination; if you go by the wrong road, you will probably not arrive." The writer is very glad that the Committee has been continued, and he submits the foregoing humble suggestions in the hope that they may have some bearing with respect to the future report which it is assumed that the Committee will make.

With respect to the actual findings of the report, the writer agrees in the main with the minority views of Mr. Knowles. Though it is true that many of the sentences which Mr. Knowles proposes in substitution are, in the opinion of the writer, merely improvements in English composition, they do add to the judicial temperament of the report.

The Committee's conclusions (page 1228) with respect to reforestation may or may not be correct. The writer believes that they are incorrect, but, assuming their entire correctness, it is apparent, to the unbiased readers to whom the writer has submitted this paragraph, that the Committee has either consciously or unconsciously made a seemingly judicial statement which, among legal brethren, would be regarded as a very adroit special plea. The half-truth expressed in this short paragraph does more to convince the reader against reforestation than would the plain blunt statement that forest growth has no effect whatsoever. Paraphrasing the concluding words of the statement, the Committee, with equal truth, could have said: "But there has been no quantitative determination of its influence on stream flow which would justify its exclusion as a method of flood prevention." The writer is familiar with intensive investigations, the results of which have unfortunately never been published, which show mathematically that forest growth does, under certain conditions like those prevailing

Mr. Leighton.

in the White Mountain region of New Hampshire, markedly reduce or meliorate flood extremes.

The Committee has disposed of reservoirs and detention basins as factors in flood prevention by a few short, obvious, and rarely disputed statements. They give the reader the impression that the Committee, on the whole, is doubtful concerning reservoir efficiency; yet, after one thoroughly analyzes the section, he may be able to agree with every statement and still remain a pronounced advocate of reservoirs. This advocacy does not commit any one to the reservoir theory under all circumstances and conditions. It merely commits the believer in reservoirs to the old common law doctrine that every cause is entitled to its day in court. An apparently reluctant admission, such as that made by the Committee, that reservoirs may be beneficial under some conditions, cannot act as a counter-weight to a series of objections and adverse implications which may or may not apply in any particular case. There is, to say the least, a lack of fairness in a pronouncement which gives qualified approval to reservoirs and then cites a series of adverse conditions without also giving to them equal and well-merited qualifications. Altogether, Mr. Knowles' expression "damning with faint praise" is applicable and well-chosen.

The Committee has wisely set forth the deficient and unsatisfactory condition of available stream flow data. It might, with equal wisdom, have set forth the unsatisfactory condition of our knowledge with respect to detailed topography, reservoir sites, and storage management. These deficiencies have been apparent for a score of years. What has the American Society of Civil Engineers done to correct that condition? Federal and State appropriations for such investigations have either been lacking or inadequate, but that is a natural consequence of the lack of information on the part of the people. It cannot fairly be expected that any considerable body of voting citizens is going to become enthusiastic over a fundamental engineering necessity which they do not understand. Who is there to explain and instruct, except the engineers of the country? The lack of appropriations is not entirely responsible for the paucity of data. Some of the blame can be traced to the inefficient expenditure of the money that has been provided. In making this statement, the writer does not intend to reflect on any particular State or Government Bureau, and, if he were disposed to make comparisons, there is one particular Government Bureau which he would exclude from this category, because it has come pretty close to making each dollar produce results to the value of two dollars. The fact remains, however, that engineers, and especially those in official life, have not expended their efforts and appropriations along the most purposeful lines. Looking back over the history of river hydraulics in America, we commonly start with the work of Humphreys and Abbot on the Lower Mississippi.

That classic investigation had one bad result. The engineers accepted it as a finality rather than a most remarkable beginning. Perusal of the reports of investigations that took place during the 25 or 30 years subsequent to the Mississippi investigation will show that the efforts were largely devoted to an attempt to prove how eternally right or how grievously wrong were Humphreys and Abbot. Had our work on river hydraulics during those years been a forward movement, rather than a *post mortem*, our present Committee on Floods and Flood Prevention would undoubtedly have found itself less embarrassed by a lack of fundamental data. A recital of past errors is useful only in so far as it may serve as a guide to future conduct. This Flood Committee could, if it desired, do more than merely report regretfully the deficiencies in our fundamental facts. It could, if it chose, become the fountain head of a campaign by which a beneficial change of conditions could be brought about. Mr. Leighton.

CYRUS C. BABB,* M. AM. SOC. C. E. (by letter).—This report is a good, concise statement of our present knowledge regarding floods and flood prevention methods. It brings out forcibly the lack of adequate engineering data on this extremely important subject. Mr. Babb.

It may be that the data collected by the Special Committee are too voluminous for detailed tabulation in a comprehensive report, but it would seem as though a bibliography or reference table of such data, arranged by drainage areas where possible, might be published with profit to the Society.

It seems to the writer that the Minority Report by Mr. Knowles contains, in a few cases, better expressions for the same ideas than those submitted by the majority. The second heading is a more fair presentation, giving the advocates of reforestation an even standing with the opponents.

The writer is in hearty accord with Mr. Knowles' twelfth heading and of placing it at the end of the report. It would seem as though the U. S. Geological Survey, through its Water Resources Division, was the proper bureau to carry on the investigation. This Division might well be elevated to the rank of an independent bureau, as was done a few years ago in the case of the U. S. Reclamation Service.

KENNETH C. GRANT,† M. AM. SOC. C. E. (by letter).—Experience in connection with flood prevention legislation and investigations has strongly impressed on the writer the value of a carefully prepared report on the general subject of floods and flood prevention, such as has recently been submitted by the Special Committee. Such a report, to measure up to its greatest possible usefulness, should deal with every possible phase of the subject, and should set forth clearly the Mr. Grant.

* Rhodhiss, N. C.

† Washington, D. C.

Mr. Grant.

advantages and disadvantages of every known method of solving the flood problem. It is particularly gratifying, therefore, that the Committee has been continued, with opportunity for written discussion by the membership at large, in order that the Committee may have at its disposal the complete information necessary to make its final report the most comprehensive and authoritative document on the subject to date.

The writer is in accord with the position taken by Mr. Knowles in the second paragraph of his minority report. The report of the Committee will do the most good if it presents both sides of disputed questions, with the reasons for and against, and points out, wherever possible, the line of investigation needed to throw additional light on the problem.

A case in point is the opinion of the Committee regarding the use of reservoirs for more than one purpose. Engineers in America have not had sufficient experience with intensive, extended rainfall and stream-flow studies to enable them to state conclusively that reservoirs cannot be manipulated in such a way by flood-warning stations that part, at least, of their capacity can be used for more than one purpose The writer has examined a number of large reservoirs which are being operated successfully in this manner in Germany and Austria. Such combined use is especially feasible in regions where floods are confined to one season of the year. Rigid supervision of the construction, and especially of the operation, of such reservoirs by some competent authority is, of course, absolutely essential.

Another case is the treatment by the Committee of the subject of reforestation. The writer would be glad to see the report point out that sufficient data are lacking to prove whether reforestation does or does not regulate stream flow sufficiently to justify its use for that purpose; that if it does have a tendency to reduce flood flow, the partial prevention of floods by such a means would be a slow process, not feasible in any situation where immunity from floods was required at once, although it should be carried out to whatever extent feasible, as a contributory benefit to stream regimen; that reforestation, by preventing erosion, does prevent the filling up of regulated channels, reservoirs, and detention basins, and thus indirectly does assist in flood prevention; that in many cases, even if it were proven effectual, it could not be applied, owing to the value of the lands in the drainage area for other purposes; in short, giving the results of the findings of the Committee on both sides of the question.

An interesting quantitative analysis of the effect of forests on flood run-off was worked up by the French Engineers, in studying plans for flood prevention on the Seine, after the great flood of 1910. Their figure for the depth of rainfall absorbed by forest cover was about 0.41 in., to which they added about three times this quantity for the

rainfall used up in 10 days by transpiration. With these figures, the action of 10 000 acres of forest cover in preventing run-off is equivalent in 10 days to a storage reservoir capacity of about 60 000 000 cu. ft. Mr. Grant.

The cost of reforesting 395 000 acres in the Seine Basin, including the cost of land, planting, and care, was estimated at $84 400 000. In 10 days this would reduce the flood volume by 2 370 000 000 cu. ft. The cost per million cubic feet of flood water retained by forest cover would thus have been $35 600, about half of which would have been returned in 60 years from the main cut of the timber. This was too high a figure to be considered, especially as the total volume of the 1910 flood at Paris during the maximum 10 days was 70 600 000 000 cu. ft., and during the entire flood was 247 100 000 000 cu. ft.

The French engineers, therefore, recommended that the Government should not take up the reforesting of the Seine Basin directly; especially as they considered that the action of heavy forest cover in retarding run-off disappears almost entirely in the great rainfalls that cause the Seine floods; and also considering the rich agricultural lands that would be taken up for forests. Their decision was that the Government should encourage all works of forest culture, should preserve intact the dense forests then existing, by improving the methods of cutting, and should lighten taxes on forest property.

Popular discussion of the causes of floods has laid so much emphasis on the influence of drainage that it would be helpful if the report discussed this subject. In some cases, properly executed drainage works increase the capacity of the drained lands for retaining water, and improve the soil cover. Furthermore, when irrigation and drainage are combined, increased retention is obtained. In any event, the needs of the improvement of cultivation in most cases notably outweigh any damages resulting therefrom.

As a means of retarding run-off, decreasing erosion, and increasing seepage in mountainous and hilly country, horizontal ditches have frequently been discussed by European engineers, but their use has been recommended only in rare cases. Suitable places for utilizing this method are not available to any great extent. They interfere with the use of the ground for other purposes. The cost of construction and maintenance is also too great. If 4 in. of rainfall are to be held back, these ditches must be about 3 ft. deep and 3 ft. wide, and require from one-sixth to one-fourth of the total land surface thus treated. At 30 ft. apart, about 1 450 lin. ft. would be required per acre, or about 928 000 lin. ft. per sq. mile. The cost would be from $13 000 to $26 000 per sq. mile. Such works favor irrigation by keeping up a dampness in the soil and increasing the supply of groundwater. An advantage of this method is that it may easily be carried out by private individuals. It is practised by the farmers of the Cevennes Mountains, in France, and in Tunis.

Mr. Grant.

The last paragraph under (*e*) *Levees*, on page 1226, may be misleading. Unless its exact meaning is studied carefully, it may give the impression that the decrease in valley storage, by confining the water between the levees, had been lost sight of. The comparison between possible methods of protection may be made clearer if it is granted, in the first place, that the lands behind the levees must be given the same protection by each method considered.

Levees of suitable size will protect the low lands behind them. The volume of water stored between the levees will be very great. To give the same protection to these lands without levees would require that this water be stored elsewhere.

It might be stored in a channel excavated to give the same cross-sectional area as that provided between the levees. This would generally be much more costly to build and maintain than the levees. There might be serious complications at the mouths of the tributaries and at the mouth of the river. The ground-water conditions might be very harmfully affected. The added cost at bridges would be very great.

It might be stored on the drainage area above, if sites could be found. The total capacity of such storage basins would have to be much greater than the storage space between the levees, in order to take care of variations in distribution of flood rainfall, and to make up for the reduction in the effect of storage that takes place in passing down stream.

One statement in the paragraph alluded to may be questioned, unless the writer has not fully gathered its meaning, namely, at the end of the first sentence: "the resultant reduction of flood height from this cause". It is unquestionably true that the artificial storage between the levees is not so great as the natural storage that was available over the lowlands along the river before the levees were built, and that this reduction in storage raises flood heights. At the same time, the contraction of the flood flow between levees raises flood heights at and up stream from the stretch of river that has been leveed. When adequate levees are built to above this increased flood height, and properly protected and maintained, they afford one of the surest and safest means of flood protection.

In view of the action of levees in reducing natural storage and thus increasing flood heights, especially in the river below, proper precautions should be urged that such improvements be not made on any reach of a river until adequate provisions have been made at other points to take care of the changed conditions of flood flow. There are points here which can well be considered in discussion of the Report of the Special Committee on A National Water Law.*

* *Proceedings*, Am. Soc. C. E., for December, 1915, pp. 2747–51.

Mr. Grant.

The French water laws specifically name what rivers or stretches of rivers may not be leveed to above maximum flood stage. On the Loire, wide overflow spillways have been provided on the levees to allow temporary storage in the lowlands behind them during extreme floods. It has for years been a subject of discussion and investigation in Austria and Germany as to whether the levees could not be altered so as to keep out only the lower floods of the growing season, and allow the great winter and spring floods to overtop the levees and spread over the lowlands. The reduction of flood heights thus obtainable is one argument in favor of such treatment; another is the fertilizing action of these silt-laden waters on the lowlands behind the levees, and great stress is laid on this feature in all reports on the subject. The overflow areas in the German river valleys are to-day only about one-fourth to one-fifth of their natural and original extent.

The natural storage effect on the overflowed lowlands along a river may be very considerable, and may have an appreciable effect in lowering flood heights. In the Miami Valley above Dayton, the valley storage in the 1913 flood amounted to about 300 000 acre-ft., or 32% of the total run-off from the 2 500 sq. miles above Dayton during the maximum 3 days of the flood.

On some rivers a disadvantage of building levees reaching to above high water is that the lowlands behind the levees are no longer raised by deposits, and sometimes even sink lower; and the river itself may gradually raise its bed by deposits in its middle and lower course, where the slope is flat. These lowlands can even gradually become swampy, and the pumps formerly used for freeing them of water in the spring only will have to be kept at work longer. This is especially to be feared in the lowlands on low deltas, which are gradually extended into the sea by deposits of silt, so that the raising of the water surface in the river is necessary, in order to create the fall required for discharge through the longer channel.

On the other hand, the narrowing of the channel by levees, by increasing the velocity, is oftentimes not only favorable for transportation of silt, but indeed forms the only available means for preventing a raising of the river bed. Without the levees, the banks and land immediately bordering them would be gradually raised, and lowlands farther back would remain low; and sometimes rivers would break through and seek a new channel in the lowlands, with disastrous results. This danger is especially great in the upper courses of rivers, where the slope is steeper. The levees reaching to above high water there form the only effective means of preventing this.

In channel improvement by deepening and straightening, due consideration should be given to the effect on ground-water conditions. On the Weser River, in Germany, agricultural interests have required

Mr. Grant.

large expenditures in order to restore the ground-water conditions that obtained before the channel was deepened.

It is important, in connection with later plans for channel improvement, that some suitable agency be authorized to exercise control over the placing of obstructions in and along streams. The cost of adequate channel improvement in some localities is greatly increased, and sometimes made prohibitive, by structures that should never have been allowed to be built in their present location or to their present dimensions.

On some rivers, particularly where melting first takes place on the upper river, as on the Oder and Weichsel in Germany, the formation of ice jams is a frequent cause of floods. The design of improved channels on such rivers should take this into consideration. In special cases ice-breaking steamers may be found necessary to prepare for spring freshets from the upper river.

Detention basins as a means of flood control are stated by the report to be successful in certain localities. This method, as yet little used in America, should perhaps be discussed in more detail. There are localities where this is the only kind of storage feasible. The agricultural lands may be too valuable to be dedicated to permanent storage. Floods may not be confined to any one time of year, so that where the drainage areas controlled are small and floods collect too rapidly to permit the emptying of a partly full reservoir in time to provide the required flood storage space, all the capacity intended for flood control must be kept empty, and ready for immediate use. In such cases, if the entire capacity available is required for flood storage, a "dry" reservoir is the only type feasible. Detention basins, as compared with reservoirs, have the disadvantage of wasting the stored flood water; and in some localities this may be a very important consideration; but, where the foregoing conditions prevail, and where flood control is a vital enough issue to warrant their construction, they will sometimes be found the best solution of the problem.

Where assurance can be had of competent and permanent supervision and maintenance, detention basins can be made much more effective by providing artificial control. Where there are no gates in the outlet conduits, they must be designed so that the maximum flood will just reach the spillway when the inflow has fallen to the same rate as the outflow. This, however, gives a much less degree of control over smaller floods than could be obtained by the manipulation of gates in the outlet conduits.

The great advantage of detention basins is that they do not remove the land in the basins from cultivation. In the Miami Valley, where the conditions for this method of flood control are particularly favorable, the total area flooded in the five proposed basins, with a flood like that of 1913, would be 29 850 acres. More than 60% of this same land (18 700 acres) was actually flooded in 1913. After such a flood all the

FIG. 1.—PINAY DAM ON LOIRE RIVER ABOUT 7 MILES ABOVE ROANNE, FRANCE.

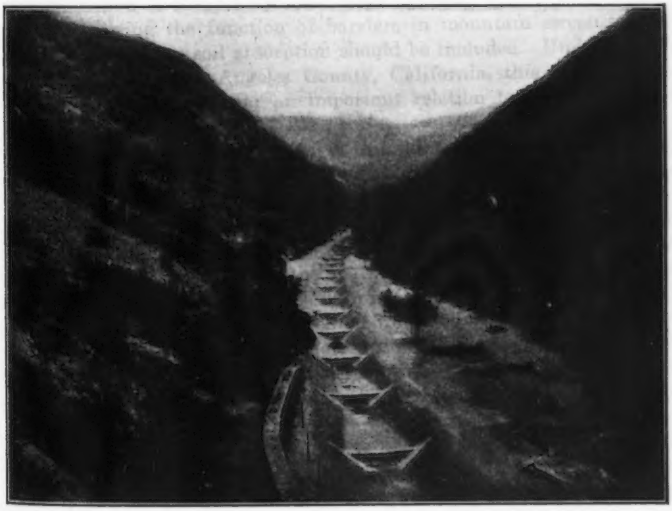

FIG. 2.—TYPICAL EXAMPLE OF WORK OF REFORESTATION AND MOUNTAIN-TORRENT CONTROL ON HEAD-WATERS OF ELBE RIVER.

reservoirs except one would empty again in a week, and that one would take about 3 weeks. In smaller floods, they would flood less land and empty much more rapidly; and, even in extreme floods, a large part of the area would be flooded for only a few days. The area actually flooded in 1913 in the Miami Valley above Hamilton was 63 000 acres, or more than twice as much as would have been flooded in the detention basins if they had been in operation. Of this flooded area, 13 000 acres were in cities and towns. Mr. Grant.

Fig. 1 shows the Pinay Dam, on the Loire River, about 7 miles above the City of Roanne in France. This is one of the most interesting examples of a detention basin in Europe. It was built by the French Government in 1711, and has since repeatedly saved the city from destruction.

It should be pointed out, in discussing reservoirs, detention basins, and levees or other channel improvements, that in many cases no one method may provide an adequate solution of the flood problem, but the best plan will consist of a combination of two or more methods. It may be found unfeasible or uneconomical to reduce flood flow to existing channel capacities by reservoir or detention-basin control. It may be found equally unfeasible or uneconomical to provide an adequate channel to accommodate maximum floods. Protection by one method is best carried out up to the point where the remaining necessary protection is cheaper by some other method.

In discussing the function of barriers in mountain streams, their action in increasing soil absorption should be included. Under certain conditions, as in Los Angeles County, California, this may be very considerable, and may bear an important relation to other phases of the water problem.

The important action of barriers in holding back sand, gravel, and boulders from improved channels and reservoirs below should be brought out more definitely. In some of the comprehensive river improvements of Europe, reforestation and *Wildbachverbauung* form an integral part of the reservoir systems and channel improvements, and are regarded as essential to the maintenance of such works on the lower streams. The River Regulation Commission of Bohemia has been carrying on a remarkably well co-ordinated work of this character on the upper Elbe, including reforestation, barriers on mountain torrents, flood-control reservoirs and channel improvements.* Fig. 2 shows a typical example of the work of reforestation and mountain torrent control on the head-waters of the Elbe.

The report makes no reference to the method of reducing floods by spreading over permeable strata. It would be helpful if it would take up the advantages and disadvantages of this method and its re-

* *Engineering News*, October 15th, 1914.

Mr. Grant.

lation to underground storage, and make some reference to localities where it has been or might be applied successfully.

Desynchronization of tributary flood peaks is an effective means of flood prevention in particular cases. It will generally be insufficient by itself, but will lessen the work to be done in connection with other methods with which it may be combined. In mountain streams, tributary flood peaks that reach the main stream at or after the passage of the flood peak of the latter can be retarded further by barriers or small detention basins, and those that arrive early can be accelerated by the improvement of their channels.

The same process on a large scale can sometimes be carried on with the larger streams, farther down. A flood wave can be made to travel twice as fast without any increase in the average velocity of the water, by establishing the proper cross-section. It can be demonstrated that, with a parabolic cross-section the speed of propagation is approximately four-thirds of the average velocity. Tributaries that deliver their flood peaks early can thus be further accelerated without any increase in erosive action. Other slower tributaries can be further retarded, where feasible, by reservoirs or detention basins, or by wide overflow areas along the banks.

Obviously, in solving the flood problem of any river basin, it is very important to avoid the more perfect synchronization of tributary flood peaks that might be brought about by reversing the treatment just outlined. It would be dangerous, for example, to construct detention basins or provide overflow areas on tributaries delivering their flood peaks early, unless the basins were large enough and the outlets small enough to reduce the flood wave sufficiently to preclude any possibility of aggravating the flood conditions on the main stream. In the same way, as a general principle, it would be unwise to speed up the flood wave on a slow tributary.

The report might well include some reference to flood prediction and its value in preventing or reducing flood damage. This is a measure of relief that can be applied at once, pending the construction of flood prevention works. It has been very thoroughly worked out in some European countries, but has not yet been developed to its full possibilities in the United States.

The figure quoted in the report for the flood losses in 1913 in the Ohio Valley is much too small. The direct property loss in the Miami Valley alone was about $70 000 000, and to include the loss through depreciation would greatly increase this figure.

The writer joins most heartily with the Committee when it urges more thorough, intensive, and co-ordinated studies of matters relating to flood control. Such investigations should include all data necessary for the solution of problems of water conservation and stream control, in order that flood prevention works may be co-ordinated with

other uses of the streams. Enormous appropriations for river regulation and water conservation have been urged before Congress for some years. If these appropriations were to be made to-day we would not have the data with which to design, intelligently and economically, the works to carry out the purposes thereof. The proponents of such measures would do far more good in the development of the country's water resources if they fathered successfully a bill appropriating several million dollars a year for the use of the present Government agencies now struggling to collect data with pitifully inadequate funds for operation. Mr. Grant.

In nearly every problem of river control attacked by the engineer in America, he finds himself confronted with almost a blank wall of lack of data, and is obliged to make safe assumptions that greatly increase the cost of the work. River gauging stations are too widely scattered, and lack of funds prevents their efficient operation. At many of them the gauge is read but once daily, so that there is no complete record of flood peaks, as they frequently occur between readings. The number of rainfall stations should be very largely increased, and hourly readings should be taken during rain storms. It is not possible, with the present methods of collecting and recording rainfall data in the United States, to determine successfully the relation between rainfall and run-off.

The writer would be glad to see the report make definite recommendations to remedy this condition.

B. F. Groat,* M. Am. Soc. C. E. (by letter).—A reading of the Report of the Special Committee on Floods and Flood Prevention, the Minority Report by Morris Knowles, M. Am. Soc. C. E., and the subsequent discussions by Messrs. Eakin and Hill, discloses the fact that the report does not seem to cover all the ground expected, and that possibly suggestions in more definite language as to general policies and methods would be acceptable. Mr. Groat.

It appears to the writer that the whole question of flood control is necessarily indefinite at present and probably will so continue for a long time. The indefiniteness and uncertainty of such a report, therefore, is a natural and certain consequence of the circumstances and present state of knowledge of the subject, rather than a result of any neglect or lack of thoroughness on the part of the Committee. Under the circumstances, one can scarcely expect a committee to devise revolutionary constructive policies, or express conclusive opinions, concerning a question which has perplexed all the rest of the world since the idea of national flood control developed and raised itself from a special to a general engineering problem, intimately related to that of national conservation. At least, this is the opinion of the writer, who is more or less of an exoteric with regard to this particular subject.

* Pittsburgh, Pa.

Mr. Groat.

Mr. Knowles' objections to the report appear to be based largely on phraseology which he considers to be single-viewed, and to partake, so to speak, of the prejudice of the Committee. The writer believes that a committee report is no place for the individual opinions of the members, except when expressly stated to be such, and that where controversial matter is involved, the evidence on both sides should have equal publicity. Engineering questions are not to be settled as are questions of law—by arbitrary rule—but they should lead to the determination of a rule, or procedure, which shall meet with either general approval or the specific approval of the Engineering Profession.

As regards breadth of view, there does not appear to be much room for exception, and it must be observed that, with the amendments suggested, the report would be even more indefinite than without, as should be expected in the case of this subject, except that Mr. Knowles does ask for additional kinds of data, as well as an increase in the quantity of such data as are now regularly observed by various agencies. The Government agencies might increase the variety by adding such information as data on erosion and transportation, precipitation for various altitudes at the same place, and for different places and circumstances, especially in higher altitudes and in sparsely settled districts. Some systematic method might be recommended for the study of forest reaction.

The most important policy suggested by Mr. Knowles is that briefly outlined in the last paragraph on page 1234. It appears to be admitted by all that the whole question of floods and flood prevention is of vital importance, and demands special efforts and expenditures commensurate with the difficulties encountered. Why not, therefore, have a "special agency, supported by adequate appropriations, for the purpose of studying stream regulation in its largest sense?"

Mr. Chittenden.

H. M. CHITTENDEN,* M. AM. SOC. C. E. (by letter).—The writer does not fully understand the purpose of a report of this character, whether it is simply to remain as the findings of the Committee, or, after discussion, to be adopted, with possible modification, as an official expression by the Society. There are certain reasons why the latter course, if practical unanimity could be arrived at, would seem, at the present time, to be particularly desirable. From this point of view, the writer will contribute his mite toward the further elucidation of certain features of the Committee's able treatment of the subject.

Terminology.—First, as to terminology and verbiage: Ought not "control" to replace "prevention" in the title? Prevention is not broad enough. Levees, for example, do not prevent floods (they actually increase gauge height and discharge), but they control them. Reservoirs prevent, or tend to prevent, floods. The comprehensive word is "control," with a logical subdivision into measures for flood forecast or

* Gen. Chittenden, who lived at Seattle, Wash., died since writing this discussion.

warning, measures of prevention, and measures of protection. The distinction between prevention and protection is well brought out in the report of the Pittsburgh Flood Commission. Mr. Chittenden.

On page 1219, under "Suggested Methods", Subdivision (*a*), on the first line, should not "rainfall" be "run-off"? Man cannot reduce "extreme variations in rainfall", as the Committee correctly states in the last paragraph on this page, but he may reduce extreme variations in the results of rainfall.

Would it not be well for the Committee to recommend the definite adoption of one or the other of the equivalent terms, "drainage area", and "water-shed". The term water-shed was formerly used, and occasionally is still used, to signifiy "divide"; but its use is now almost universally confined to a designation of the territory drained by the particular stream under consideration. Probably no confusion results from the use of both terms, but simplicity of terminology is always desirable. The writer favors the term water-shed.

Several designations have been applied recently to the comparatively novel system of flood prevention which is the distinguishing feature of the great flood-control project being worked up by the Miami Conservancy District. These include "dry reservoirs", "detention reservoirs", "detention basins", and "retarding basins". When the writer was preparing his paper on Flood Control for the recent International Engineering Congress in San Francisco, he gave this matter some little consideration. Inasmuch as reservoirs may properly be classed in two distinct types, dependent on their purpose and functioning—those designed to store water for future use, and those designed to detain it temporarily for flood prevention only—it seemed wholly logical to use "reservoir" (Latin, *re servare,* to hold back) as the generic term, so to speak, and "storage" and "detention" as specific designations. It was for this reason that he felt particular about adopting "reservoir" as against "basin". The Miami Conservancy District has definitely adopted "retarding basin", and the prominence of this example ought, perhaps, to settle the question.

Effect of Human Occupancy of Soil.—The writer feels that the Committee might advantageously have been more definite and positive in its discussion of this subject, particularly as it relates to the value of reforestation. For reasons stated later, a definite pronouncement on this subject by a professional body like this Society would have a most important influence. Doubtless, there is some reluctance to assume a positive attitude on a question which, as Mr. Knowles says, is "one of the most controversial subjects upon which engineering and scientific minds have been recently engaged." It may be questioned, however, whether to-day there is much controversy among well-informed engineers as to the essential principles involved. Is not the consensus of professional opinion that, in times of excessive rainfall, in which

Mr. Chittenden.

really great floods always originate, the restraining effect of forest cover, whatever it may be in ordinary storms, becomes exhausted and is of no effect? This is the official opinion in France, even in forestry circles, as is shown by the following extract from a report by the Director of the French Forestry Service on the 1910 flood of the Seine:

"In the exceptional circumstances which always produce the floods of the Seine, the action of forests, whether evergreen or deciduous, becomes for the moment negligible in its effect on the volume of water carried by the river."*

Engineers are apparently agreed on this essential point. In formulating plans for flood control, they would not dare to reduce in any degree the effectiveness of direct measures, such as reservoirs, levees, etc., by any possible measures of reforestation. The Committee brings out this point in the first paragraph of page 1224 of its report, but it weakens its position by holding out the questionable hope, implied in the words "not at present susceptible", etc., that the future may demonstrate a value in forest cover not at present apparent. Mr. Knowles, on page 1231, is outspoken in the expectation that "quantitative determination" of the effects of forests on run-off is a possibility of the future. The writer dissents wholly from that opinion. The difficulties in the way of any such result are practically insuperable. A determination for one situation, or season, or storm, would never apply reliably to any other. The modifying influences are infinite in detail, and the utmost that we can hope for is a gross integration of results, as shown in the records of stream flow. This has already been carried on in Europe for more than a hundred years, with a wholly negative result so far as the favorable influence of forests in reducing run-off is concerned. It seems very desirable, therefore, that a report of this character should not hold out any false encouragement.

At this point, it may be well to consider a feature of the subject not mentioned in the report, yet a most important one, and one concerning which there may be differences of opinion, even among engineers. Reference is made to the influence of drainage on flood run-off. The obvious and plausible inference is that drainage—roads, pavements, sewerage, farm ditches, tile drains, etc.—expedites the run-off and fills up the streams more rapidly than formerly; but there are very strong counter forces which operate to retard run-off, particularly from originally wet and marshy soil and from swamp areas. This is the creation of ground storage where none existed before. The very

* "Mais, dans les circonstances exceptionelles dans lesquelles se produisent toujours les crues de la Seine, l'action des forêts, fussent-elles résineuses ou feuillées, devient momentanément négligible sur les volumes des eaux roulées par le fleuve. Les pluies intenses et persistantes de la seconde quinzaine de janvier dernier, ayant saturé le sol forestier, commes les autres terrains, les eaux tombées à la surface sont toutes allées aux thalwegs." M. Daubrée, Conseilleur d'Etat, Directeur Général des Eaux et Forêts. Report of First Commission on Flood of 1910 in the Seine, p. 515.

purpose of drainage is to get water out of the ground; but when so gotten out, space is left for other water. The most effective and instantaneous of all reservoirs, so far as flood control is concerned, is the top 18 in. of soil, depending on the extent to which it is saturated. A swamp soil undrained is generally thoroughly saturated. It comes next to an actual body of water in that respect. The only, or the main, storage available is surface storage due to the conformation of the basin. Drainage takes the water out of the swamp soil and creates vast storage space where before none existed. This effect is fully recognized by the French. It is, of course, greatest with summer or early fall storms. Like all surface storage, it may become greatly reduced or completely exhausted by the long rains of winter. Mr. Chittenden

With the utmost that can be done in attempting to evaluate the influences of man's occupancy of the soil in modifying the effects of soil cover and absorption, we find it impossible to say on which side the balance lies. It is probably not important, either one way or the other, and, in any event, becomes wholly obliterated in those excessive rainfalls which alone produce great floods. This conclusion harmonizes both with theory and stream-flow records, and should be accepted as definite and final. The writer emphasizes it, not because the popular view to the contrary influences the engineer to any great extent, but because it does influence the legislator to whom the engineer often has to look for funds, and it thus, in the words of the income tax law, "deducts" from his power of effective action "at the source". How great is the importance of taking a definite stand on this question may be judged when a distinguished United States Senator, who pretends to some acquaintance with these subjects, and whose opinions carry weight in legislation concerning them, is capable of delivering, in apparent soberness and good faith, an utterance like the following:

"We have been destroying our forests, great natural reservoirs of moisture into which the waters fall from the heavens, and where they are stored in the leaves and in the loose soil, and drunk up by the thirsty roots of the trees and vegetation, and thence the surplus gradually makes its way to the creeks and tributaries of our rivers, and the water which used to be absorbed by these forests is now hurried on into the creeks and rivers."*

* Hon. Francis G. Newlands, in the United States Senate, Feb. 21st, 1916. It is interesting to apply this to a particular case. In the country around Dayton, Ohio, in March, 1913, after heavy winter rains had quenched to satiety any thirst from which tree or other roots might have been suffering, there fell, in a period of 4 consecutive days, between 9 and 10 in. of rain, or more than one-fourth of the average for an entire year. Assuming that the virgin forest had still covered the country, what percentage of this deluge does Senator Newlands imagine would have been "drunk up by the thirsty roots?" And what is Senator Newlands' warrant for calling the soil of the forest "loose"? Has he ever noted a great tree which has been overturned by the wind and has carried up with its roots perhaps 100 sq. ft. of soil so densely compacted that it resists for years exposure to the elements? The truth is that virgin forest soil, undisturbed for ages, is one of the most compact of soils, whereas cultivated soil, ploughed and harrowed and worked over, and full of perennially decaying roots, has the maximum absorptive capacity of which a given quality of soil is susceptible.

Mr. Chittenden.

If the clearing and drainage of the soil—in general terms, cultivation—do not materially affect the development and intensity of great floods, is there any respect in which man's work does enhance their destructiveness? This question admits of a definite answer in the affirmative. By obstructing Nature's overflow channels Man draws on himself the chief calamities which floods produce. The bottom lands along streams are just as much a part of Nature's highway for carrying run-off to the sea as the normal channels between banks. They do not come into play so continuously, but they are a part of the natural waterways, and were formerly so used whenever the discharge rose above a certain volume. Man has pre-empted these channels entirely. They contain the most fertile lands, they are easiest to build on, and most convenient for roads and railroads. It is here that population multiplies and wealth accumulates, and whenever Nature asserts her old prerogative of passing her floods down over them, trouble ensues. By cutting off these bottoms, greater work is forced on the ordinary channel, the flood heights are raised, and if once the waters break their bounds, they not only find wealth and people in their way, but are actually far more destructive than in their natural state. Thus Man is, to a large extent, the author of his own misfortunes in the matter of flood destructiveness. The point here emphasized, however, is that Man's interference with natural conditions, which so often leads to disaster, relates to his trespass on overflow channels rather than, as is popularly assumed, on the normal channels of the streams themselves. Contrary to general opinion, Man's operations have, on the whole, improved the natural carrying capacity of streams. There are exceptions, of course, but the rule seems to be as just stated. A striking example is furnished by the recent studies of the Great Miami River, in Ohio. In the four principal towns, where channel changes have been most important, the discharge capacity was found to be from two to eight times as great as in the country above and below, where Man's interference has been slight. Such a condition, of course, cannot be accidental.

The foregoing remarks disclose the reason why flood destructiveness is increasing. It is not because floods themselves are increasing, either in frequency or intensity, but because property subject to destruction is very greatly increasing, and as yet protective work does not keep pace with this increase. In time, this disparity will disappear, or rather be reversed, and flood destructiveness will then show a decrease. Some railroads have already carried protective measures so far that they suffer little, even from the greatest floods.

Reservoirs.—The divergence of view between the Majority and Minority Reports, concerning the conflict of purpose of reservoirs and the impracticability of utilizing the same reservoir simultaneously for flood control and other uses, is probably more apparent than real.

Mr. Chittenden.

It would seem that the essential principles are too clear to be capable of dual interpretation. In the first place, the conflict of purpose in reservoirs can be completely overcome by giving the reservoir excess of capacity over storage requirements sufficient to provide for flood control. This, however, is often impossible for lack of site (ignoring, for the present, considerations of cost), and inasmuch as industrial use, municipal supply, etc., must be on a dependable basis, it follows that they must receive first consideration. Subject to this restriction, however, storage reservoirs, as such, will generally be useful in flood prevention. It may happen that a flood-producing storm may come early, when a reservoir is filling, in which case the reservoir might be as effective as if designed for flood control only. Again, the flood storms may arrive late, after the reservoir has become full or nearly so. In that case, the discharge must go over the spillway; but, as some elevation of surface is necessary to produce the spillway overflow, and as the surface of the reservoir, and the storage per unit of rise, are at a maximum at this stage, there will be, even in this extreme case, a certain degree of control.

Nevertheless, the general principle laid down in the report holds. The engineer charged with a project of flood control, in which the use of a storage reservoir is contemplated, cannot take into consideration possible advantages which may or may not accrue. If there is a possibility that they may not accrue, he is bound to assume that they will not. He must make the most unfavorable assumption within reasonable probabilities. Having thus determined what aid can be positively depended on from the reservoir, he must make other provisions for such additional control as is required. It is right here, it seems to the writer, that public supervision of reservoir construction is demanded, and that public aid in the interests of flood control might well be given. For example, if a reservoir site is about to be developed on a stream where the flood problem is important, it might well be that, by increasing the capacity beyond what would be sufficient for storage purposes, the reservoir could also be made to serve the additional purpose of flood prevention. In that case, public aid would seem to be justifiable.

On the whole, the possibilities of combining flood prevention with other uses of reservoirs are sufficient to justify Mr. Knowles' contention that the Committee's report would be strengthened by omitting lines 17 and 18 on page 1225: "Your Committee, however, does not intend to condemn *in toto* the utilization of reservoirs for more than one purpose."

Barriers.—The comment on "Barriers", (*c*) page 1225, seems to the writer most judicious in recognizing only the function of arresting débris. Just now there is current another of those extremist propagandas which have interfered so much with scientific treatment of many of our problems by confusing the public mind with schemes the

Mr. Chittenden.

only virtue of which is superficial plausibility. Los Angeles, Cal., is the present victim. A campaign is on there to make barriers the sole, or at least principal, solution of the flood problem in that locality. There has been created a "very wide-spread furore that the only way to control the flood waters [at Los Angeles] is to build myriads of little check dams in the mountains, and, through the detritus caught above each of them acting as a sponge, to soak up all the floods before they leave the mountains."

So far as the writer has observed in reports on this subject, the primary purpose of these check dams is to prevent erosion. Not much stress is laid on their effect in storing water. They soon become filled with detritus, and this, in the general case, will become well soaked with the rains leading up to great flood storms, so that the chances in favor of any material reduction in discharge are altogether uncertain. Immediately following a dry spell, a heavy run-off might be considerably reduced, whereas, with a storm of the same intensity following a series of lesser rains, there might be practically no relief. In this, as in the case of forests, the engineer cannot build on uncertainties.

Outlets.—With some hesitation the writer offers a certain criticism of the conclusion stated in the last paragraph on page 1227. So far as he has followed the official reports on the subject, it is evident that there is an important distinction between the outlets proposed, say, near New Orleans, and natural outlets or accidental crevasses cited as militating against the outlet theory. It is manifest that the action on the regimen of a river of a great crevasse must be different from that of a long overflow weir which comes into play only after the river has reached a certain stage. The writer cannot understand why, if the river safely transports its sediment at that stage, it should fail to do so by preventing any marked rise thereafter through abstraction of the surface flow by a weir. It is very possible that the outlet channel itself might silt up and become ineffective, but that would have nothing to do with the argument just advanced.

Cut-Offs.—Having now reviewed the general features of the report, the writer desires to devote more detailed consideration to the subject of cut-offs. In general, his views coincide with those of Mr. Grunsky. He believes that the ultimate effect of cut-offs is beneficial, providing always that those reasonable and obvious precautions are taken which the circumstances of the individual case clearly indicate. He dissents from the orthodox view, so long held on the Mississippi, that that river has a sort of intelligent purpose in maintaining a particular length of channel, and that it always "seeks" to regain that length if suddenly shortened by the excision of a bend. The truth is that a river in an alluvial soil may perform almost any antics which the physical conditions will permit; but, that such a river has a definite length which

Mr. Chittenden.

it is always seeking to maintain, is an assumption not substantiated by fact, at least on other streams.

In illustration of this point, the writer presents a diagram (Fig. 3), showing the changes of a century in about a 50-mile course of the Missouri River. The early cut-off of some of the enormous bends that existed in 1804 has never resulted in any "attempt" on the part of the river, either on this section or above or below, to regain its original length. On the other hand, successive surveys show if anything a contrary tendency; and there is nothing in the long record of navigation on that stream which indicates any ill results to navigation resulting from such cut-offs.*

The writer also questions the correctness of the statement that cut-offs "increase flood heights below them", while "reducing flood heights immediately above". This may be the first effect, but it is not first effects, but permanent results, which must be considered. In the long run, the result, according to the writer's observation, is to draw down the channel above the cut-off until it comes practically to the original grade of the channel below. (It is understood that we are here considering only the case of alluvial streams in comparatively unstable channels.) In the course of time, these effects may extend many miles up stream, and the sharp change of slope at first produced may be distributed so far as to be very slight per unit of distance.

Fig. 4 is reproduced from a photograph of quite an extensive cut-off on the Missouri River which took place under the writer's observation.

The channel shortening, as he now recalls (without verification from the records), was about 7 miles. Much local alarm was felt lest the cut-off should produce a flood below. The writer tried to assure the public that no such thing could possibly happen; that the cut-off in itself would not increase the discharge of the river at all, except as to the small increment from draining the bend, and that there was absolutely no danger. Nothing would allay the fear, however, and there was much talk of taking steps to prevent the cut-off, when certain interests which wanted it to take place rendered judicious assistance (with dynamite, mainly, it was said), and the controversy was promptly settled. At the first gauge below, a rise of a few inches was detected, but no untoward result whatever happened. In this case, the writer feels certain that the final result was a lowering of the old bed above the cut and not a raising of the bed below.

The reports of the Mississippi River Commission abound in references to work designed to prevent cut-offs which might (to cite a

* One naturally questions the correctness of the early maps on which these extreme bends are shown; but, apart from the general accuracy of Lewis and Clark's work, as shown by later surveys, there are authentic references in the journals of other early voyages up the river. It never took less than a day and sometimes two days for a keelboat to get well past Blackbird Hill, opposite the neck of one of these bends, after having arrived in its vicinity.

Mr. Chittenden.

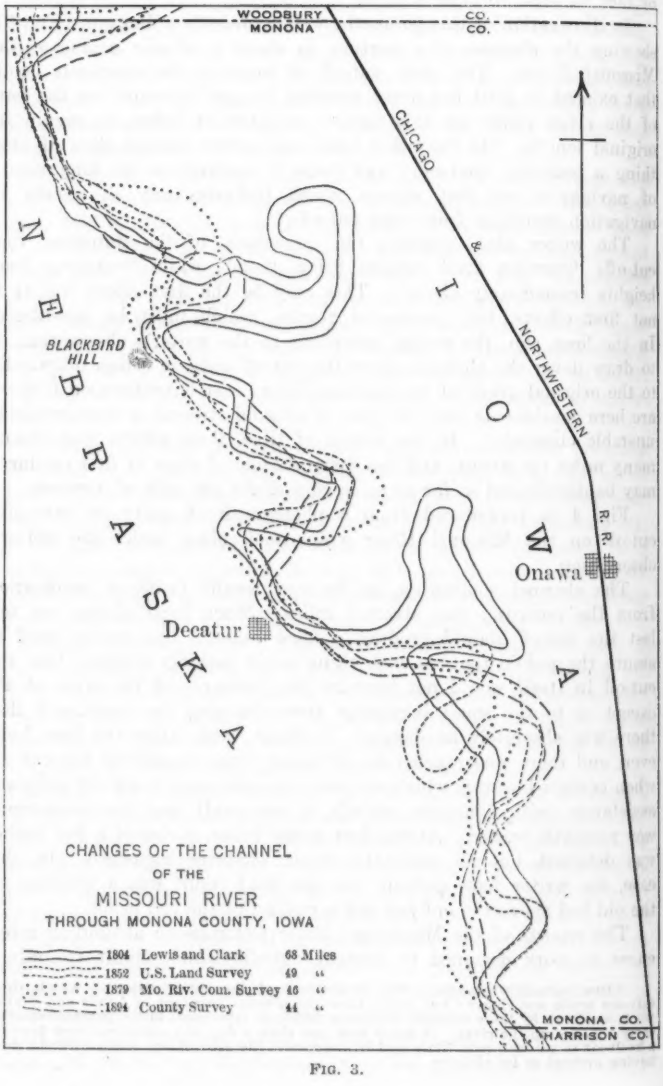

FIG. 3.

FIG. 4.—A NEWLY FORMED CUT-OFF ON THE MISSOURI RIVER. OLD CHANNEL IS TOWARD BACKGROUND ON THE LEFT AND FROM BACKGROUND ON THE RIGHT.

particular case) "disturb the regimen of the river a long distance above and below, and bring disaster to towns, levees, and other works along the river banks." The results of a cut-off that did take place are traced in considerable detail, showing how one ill effect led to another, until a heavy toll of misfortune had accumulated. All this appeals to the writer, however, as a clear case for the Franklinian philosophy contained in the parable of the horse-shoe nail. If the occurrence of this cut-off had been anticipated by timely protective work above and below, probably nearly all the ill effects which actually developed might have been avoided. The writer would not for a moment criticize official policy in preventing cut-offs on the Mississippi River; he simply criticizes the theory on which that policy is ostensibly based. He believes that the real objection to cut-offs on that stream is not the effect on the regimen of the river (which can be controlled effectively), but on riparian interests. Ports and landings might be ruined and other interests jeopardized in a way that would result in serious hardship; but, aside from these considerations, viewed only as a problem in river hydraulics, the writer believes that a material shortening (say 125 to 150 miles) of the Mississippi River between Cairo and Red River would not, in the long run, injure the regimen, even for purposes of navigation, and it would certainly make the river a better flood carrier and would reduce materially the length of channel to be maintained and of bank to be protected. Mr. Chittenden.

The writer would dissent, further, from the distinction which the Committee draws as against alluvial streams in this connection. It is, in many instances, on alluvial streams that this measure can be best applied. The difference between an alluvial stream and one with stable banks is that, in one case, disturbance of regimen may result, and, in the other, it may not, and that, therefore, in using the cut-off on alluvial streams, auxiliary measures are necessary. If these are provided, however, the shortening of the channel should certainly facilitate the natural movement of sediment down stream. Cut-offs have been used extensively on great alluvial rivers, notably on the Danube and other streams of the Hungarian plain.

The cut-off method finds its most effective application in low flat tracts in which stream sinuosity dates from the remote period of emergence of the soil from a status of continuous overflow, and is not a result of present-day processes. Generally, in such locations, the sinuosity is excessive, the slope very slight, and the channel capacity wholly deficient. Extensive cut-offs do not produce excessive slopes and troublesome erosion, but facilitate drainage and carry off flood waters more rapidly. Whether in any particular case a cut-off or series of cut-offs is desirable depends on local circumstances. The most important obstacles are cost and the likelihood of riparian complications. Another consideration relates to the excised portions of

Mr. Chittenden.

the channel. If these can be filled up, there is a net gain of land area, for the excised portion is always larger than the new channel. If they cannot be filled, there is a loss of land equal to the new channel. Even in that case, there may be some utility in the excised sections in connection with drainage. By placing flood-gates between them and the new channel, they can be drawn down to the level of low water in the dry season and then be utilized as immense sumps to maintain effective drainage during high-water periods.

Minority Report.—Concerning the several substitutes proposed in the Minority Report, some of them seem to be in the interest of completeness and precision, and some appear to the writer as undesirable. Among the latter are the proposed changes in the forestry discussion. As to (10), on page 1233, it would seem that Mr. Knowles confuses two distinct things. The fact that levees cut off valley storage previously available does not in any way alter the other fact that levees, by raising the flood surface between them, do develop a certain amount of channel storage.

It is important, however, to observe a distinction, which neither the Committee nor Mr. Knowles has brought out, but which justifies to some extent Mr. Knowles' contention that "such storage is ineffective", although for a reason quite different from that which he has assigned. It is entirely true that the volume of water at flood stage stored in stream channels, like the Mississippi and Ohio, is prodigious, including as it does not only storage in the channel proper but the filling of side ravines and tributary valleys and the overflowing of bottom lands back to high ground or levees. The natural impulse is to give such storage great weight in holding down flood heights; but this is clearly inadmissible. Channel storage is mainly absorbed in the preliminary stages of a flood. The case is similar to that of a reservoir which has been filled from the earlier rains and has no space left for the later rains; and though it may still exercise a slight moderating effect on run-off passing through it, such effect is not at all in proportion to the full capacity of the reservoir; and the more prolonged the crest of the flood is, the less will be even this attenuated effect.

The same conclusion may be reached by a hypothetical illustration: Suppose the Ohio River from Pittsburgh to Cairo to be a closed conduit, of cross-section equal to, say, the ordinary low-water section of the open channel; and suppose that, by some mechanical process, sufficient velocity could be imparted to the current in the conduit to carry away all run-off as fast as it should present itself. It is manifest that the discharge at Cairo during rising stages would be greater than with an open channel, due to the fact that no storage had been allowed to accumulate; but this difference would evidently disappear when the maximum stage had been reached and there was no further accumula-

tion of storage. At the critical point of the flood, therefore, the reservoir function of the channel ceases to have effect. Mr. Chittenden.

The writer feels the more freedom in criticizing the Committee's treatment of this matter because he is at the same time criticizing his own previous utterances on the same subject.* The conditions are abstruse and difficult to lay hold of definitely, but the writer believes that they are fairly set forth in the following statement:

Storage in and adjacent to the channel of a stream, which results automatically from an increase of stage, has little if any effect in reducing the maximum stage. It operates to reduce somewhat the rates of discharge during rising stages while storage is actively accumulating, but this effect gradually disappears on approaching the maximum stage where storage accumulation ceases.

MYRON L. FULLER,† ESQ. (by letter).—The problem which most nearly attains successful solution, whether it be one of business, science, or engineering, is that which takes into account, duly analyzes, and gives proper weight to the greatest number of contributory factors. Mr. Fuller.

Of the factors of flood control or prevention, geology is assuredly one that must be reckoned with. The far-sightedness which is essential to the satisfactory conclusion of any great undertaking demands that every known factor of the problem be considered and the weight given to it that mature investigation shows it has the right to claim.

Nothing is more true than the following statement by Morris Knowles, M. Am. Soc. C. E., in the Minority Report of the Special Committee. "It is unwise to assume that we have at any time obtained all the knowledge possible upon a given subject." Every year sees new advances in our knowledge of engineering problems; and our ideas as to the precautions necessary in engineering undertakings are continually changing. Factors hitherto unknown or neglected are almost daily found to be of importance.

Most of the great failures in engineering works, as well as in other lines of business, have been due directly or indirectly to overlooking some inconspicuous factor or neglecting some element of apparent insignificance. For example, the lack of knowledge as to the weakness and slipping planes in shales, or the failure to realize their significance, has resulted in the failure of several large dams and reservoirs within the past few years, and the inadvertent omission of some engineering factor has played an important part in the collapse of bridges and other steel structures.

The writer does not maintain for a moment that the success or failure of flood prevention or control measures is dependent on geological investigations, but he does contend that geology is one of

* "Flood Control, with Particular Reference to Conditions in the United States", presented to the International Engineering Congress, San Francisco, September, 1915, pp. 16 and 22.

† Boston, Mass.

Mr. Fuller.

the factors—sometimes one of marked importance—which should be considered in any comprehensive investigation looking to the prevention or control of floods.

Insufficiency of Precipitation Data.

Notwithstanding the great efficiency of the Weather Bureau, rainfall data, chiefly because of the comparatively short periods during which records have been kept, are admittedly insufficient for the determination of the maximum possible or even probable precipitation in a given area.

It is true that a certain approximation to the probable maximum precipitation may be made from an inspection of the rainfall records throughout the general province or climatological zone of which a given district is a part, by applying the maximum precipitation recorded elsewhere to the area under consideration. As is well said in the Report of the Special Committee (page 1220), however, "it is improbable that the maximum precipitation that may occur at a given locality has yet been recorded."

Taking the maximum rainfall recorded for the province or zone, and the maximum known accumulation of snow for the same latitude and altitude within the zone, it is possible to estimate the probable height of a flood under existing conditions of channel. The height calculated, however, is by no means free from likelihood of error, and it is entirely possible for the water to rise many feet higher than the estimated limits.

Geological Clues to Flood Heights.

Flood-Plains and Terraces.—In the absence of sufficient rainfall data, it is fortunate that geology furnishes, in many instances, a clue to the probable heights of flood-waters. The clue referred to is that afforded by the flood-plains and terraces, which often give evidences of heights of water greater than those which would be indicated by the computations from greatest recorded rainfall.

Generally speaking, there is little evidence that floods are either more or less pronounced and frequent at the present time than in the immediate past. This, of course, does not apply to the more remote geological past, when climatological conditions were radically different.

The evidence afforded by flood-plains is not altogether simple or universally present. Mountain streams, having steep gradients, are usually cutting rather than depositing, and flood-plains and terraces are commonly absent, although even in mountainous regions elevated pockets of sand often afford clues to the high-water limits. In flatter regions, such as the greater portions of the Mississippi and Ohio Basins, the streams are generally aggrading or filling their

valleys, at least locally, and are commonly bordered by flood-plains or terraces. Mr. Fuller.

The flood-plains are fundamentally constructional in origin, being built up of the relatively fine deposits laid down when the waters of the streams overflow the normal channels and spread out with checked velocity. The upbuilding continues, unless new geological or artificial factors intervene, until the surface reaches nearly the level of the highest floods. During the later stages, the upbuilding is very slow, and the floods overtop the flood-plains only at long intervals, perhaps of centuries. In the majority of localities the flood-plains have not reached their final stages, especially where, because of constrictions of the channels or other causes, the currents are unusually swift, but are still overflowed to a depth of several feet by the greater floods.

The uncompleted stages of the flood-plains introduce large elements of uncertainty, and the problem is still further complicated by the fact that portions of the once completed flood-plains may have been subsequently eroded away, leaving surfaces much lower than the levels reached by the floods. In other words, a series of terraces is left, only the uppermost members of which are of significance in determining flood heights.

If this was all, the problem would still be comparatively simple, but further difficulties are introduced by the fact that, in some instances, the whole river valley has been cut in glacial or other sands and gravels of a past geological period. In this down-cutting, terraces similar in appearance to those of the flood-plains are commonly left at various levels.

The determination of which of the general series of terraces in a given valley are due to upbuilding, and are, therefore, of significance in the determination of probable flood levels, and which are due to down-cutting, and are without present significance, is often difficult, and the discrimination can seldom be left to the engineer with safety, or even to the academic geologist of the average college faculty. The discrimination can be made, but it requires a practical and experienced field geologist to make it with certainty.

The flood-plains and terraces, notwithstanding their complexities, afford a line of evidence that should not be neglected in any comprehensive investigation of flood control. When the writer was engaged in Ohio on Government geological surveys, ten years ago, the question was several times asked in regard to towns or their water supplies: "Is there any danger from floods?" The answer was that the towns were situated on flood-plains built up by repeated overflows of the streams, and that similar overflows were bound to occur in the future unless artificially prevented. The writer did not necessarily expect

Mr. Fuller.

a flood of the proportions of that of 1913 so soon, but it was bound to come eventually.

Geological Obstructions to Streams.

Geological obstructions to streams, because of their obscurity, are often overlooked—or their importance under-estimated—in flood-control studies. Two distinct types may be mentioned: the boulder delta and the rock barrier.

Boulder Delta.—Existing deltas or fans of boulders or coarse gravel are manifest obstructions, and are recognized by engineers as such. They occur chiefly where side streams having steep gradients issue from hills or mountains into broader valleys where the streams are more sluggish and are usually engaged in building up their flood-plains. Often, the main streams are pushed aside and forced close against the opposite banks, where they flow in comparatively narrow and deep channels. They are obstructions which have an unmistakable and calculable effect on flood height.

The deltas which are not pre-existing, on the other hand, introduce important but unknown factors. A severe rain over the water-shed of a small tributary is felt almost at once, and the stream commonly responds long before the water rises very materially in the main valley. The result is that enormous volumes of material are often swept into a river, causing great accumulations of gravel or boulders where no deposits may have previously existed. It is true that, as the main river rises, many of these accumulations may be swept away, but, in the meanwhile, they are a very real obstruction, with an important influence on flood heights. Their final destruction may inaugurate flood crests endangering the whole country below. Under other conditions, the deposits may become permanent features, at least for a considerable period of years.

The boulder or gravel deltas of this type are certainly worthy of attention in flood-control studies, and geological investigations of their possible effects are highly desirable.

Rock Barriers.—In many of the valleys in the Ohio and Mississippi Basins there are buried rock channels much deeper than the general rock floors over which the streams now flow. The latter commonly mark the depth to which the scour of the river extends during flood periods at the present time; the deeper channels mark the former positions of the river under different conditions of level or discharge. Sometimes, the present channels coincide with the older rock gorges, in which case the scour may extend to somewhat greater depths. Sooner or later, however, the streams have to return to the general rock floors, usually accompanied by sudden rises in the bottoms. This has an important effect in checking flow and in promoting deposition.

Mr. Fuller.

Although the importance of the rock barrier is less than that of the delta, its influence is sufficient to warrant taking it into account in the flood-control problem.

Geological Factors of Run-Off.

The principal geological factors of run-off are: the grain of the soil, the thickness of the soil, and the nature of the underlying rock, including composition and fissuring.

Grain of Soils.—The grain of soils, using the term "grain" in its broader sense to include the arrangement and packing of the particles as well as their size, is of the greatest importance in run-off and flood studies of a given water-shed. A proper study of the grain includes both laboratory tests and field examinations. The former consist of sizing tests or analyses by passing the material through a series of standard screens of various meshes, and from them may be computed the rate of percolation under different conditions. Direct tests on blocks of soil cut from the ground, where the material is sufficiently firm to hold together, have been found, in the writer's experience, to afford still more dependable results. All measurements or estimates of rates of percolation apply, naturally, only to unfrozen soils, hence are of value only in seasons where the ground is free from frost.

Classification of Soils.—Accompanying the percolation estimates and tests mentioned—which are as much of an engineering as of a geological nature—field examinations must be made, and the soils classified, mapped, and their areas determined. These can be made best by a geologist or soil expert. Samples, at the best, can be taken at only a limited number of points, and must be supplemented by a soil classification of the entire area, if the work is to have any real value. The geologist's knowledge of the general character of residual soils, or those resulting from the weathering of different types of rock, of the nature of the various classes of glacial deposits, and of the composition of the alluvial accumulations, is of the greatest assistance in this branch of subsidiary investigations in flood-control studies.

Depth of Soil.—The depth of soil is of much greater significance than is commonly realized. The writer's ground-water studies in some thirty States have shown that rocks free from soil coverings seldom contain much water, and that the same rocks, when covered by a thick soil mantle, afford abundant supplies. Conversely, when the soil is thin, the immediate run-off is much greater than where it is thick. Therefore, geological studies to determine the depth of soil are of considerable importance in run-off studies.

Composition of Rock.—The absorptive capacity of the underlying rock is a factor of significance in flood control. The porosity or absorptive capacity varies greatly in rocks of different classes, ranging

Mr. Fuller.

Limited Value of Sedimentation Basins.

Moving water will always carry its full load of sediment if the material is available. It is a geological principle that, if it does not already have such a load, a stream will pick it up from its bed or banks until it is fully loaded. The greater portion of the coarse material under transportation by a stream is carried only a short distance. It is picked up where the current is accelerated, the scour often extending to depths of 30 ft. or more, but it is deposited in large measure as soon as the current is checked. Only the finer and relatively harmless silts become a permanent addition to the water. In the course of time, by innumerable repetitions of the process described, the coarser material is carried to points far distant from its source, but very little except the finer silts is transported to any considerable distance during a single flood.

For these reasons, it appears that, as a general rule, sedimentation basins may be expected to be of limited value, although, as local protection, they may occasionally be entirely successful.

Levees.

A levee system, by confining the current of a stream, tends to intensify the scour, and, for the same reason, subsequent deposition may be hindered. In the long run, river bank erosion is reduced, and such deposition as occurs is probably less harmful than along an uncontrolled channel.

Outlets.

The value of natural or artificial outlets depends to a considerable extent on geological conditions. An outlet may present a shorter line of discharge and a straighter course than the existing channel; but, unless the water can get into it freely, it is not likely to be utilized by a stream. The inlet to it must be free from obstructions and in line with the natural swing of the current, and the banks must not cave (in proportion to the volume of water) more than those along the existing outlet.

If any considerable volume of water follows a new outlet, temporary relief is, indeed, afforded, but the improvement is not permanent. Either the new or the old channel will soon silt up, and the final condition will be no better than before. The Hwang-Ho, in East China, shifted its mouth a distance of 275 miles in 1852, but flood conditions are said to have been accentuated rather than relieved.

Necessity for More Comprehensive Studies of Streams.

The Government, in connection with its comprehensive and detailed studies of the Mississippi and its larger tributaries, has secured very

complete data on erosion, transportation, and deposition by low-gradient streams, especially in their lower reaches. There is, however, a deficiency of data pertaining to the upper reaches and at the head-waters. Mr. Fuller.

It is evident that the conditions in the upper portions of most large streams are entirely different from those in the lower portions. In the latter, notwithstanding the wholesale caving of the banks, the excavation of cut-offs, etc., deposition predominates, and stream beds, flood-plains, and estuarine deposits are being gradually built up. On the middle reaches erosion and deposition are more nearly balanced, and the conditions as regards flood-control are essentially different. In the upper reaches and head-waters, erosion usually predominates, and flood conditions differ materially from those of either the lower or middle reaches.

In many of the smaller drainage basins, such as those of several of the Ohio tributaries, all three conditions are represented within comparatively short distances, and no one set of laws of erosion and deposition will apply. The data derived from the Mississippi studies may be applicable to the lower reaches of these streams, but there is a decided deficiency of information as to the behavior and work of the streams in their upper sections.

The result of this deficiency of knowledge of the behavior of the swifter streams is illustrated by the destruction of many railroads at various times in the past in the canyons of the West, especially along the San Pedro line between Los Angeles and Salt Lake City, which was rebuilt for long distances after its destruction by flood about 6 years ago.

The question of run-off needs more careful consideration, especially the effect on it of forestation, with a view of fixing quantitative values that may be depended on with more certainty than is now possible.

Flood depths and flood velocities in mountainous and hilly regions need more extended investigation in order that the limits of danger may be more definitely fixed. This is often even more important than similar investigations in the flood-plain sections, as the floods are more sudden, more uncontrollable, and more destructive than in regions of the latter type.

The size and nature of the material available for transportation are also important factors in floods. Structures that might withstand the water alone may fail under a bombardment of boulders, often hundreds and sometimes thousands of pounds in weight, which are swept along by mountain torrents. More information is also needed as to the effects of bends of various radii in the canyons and valleys, as well as the influence on floods of narrowings of the valley walls.

Mr. Fuller.

Many of the factors mentioned are geological in their nature, and their investigation would naturally take place in connection with that of the numerous other geological problems involved in flood regulation or control.

Final Statement.

A few of the geological factors entering into the problem of flood control and prevention have been stated briefly. Many others would undoubtedly develop in the field. The writer believes that some of these factors will be generally acknowledged as of unquestionable importance. At any rate, it is not safe to pass them by without mature consideration in any broad investigation of floods.

Mr. Matthes.

Gerard H. Matthes,* M. Am. Soc. C. E. (by letter).—The writer endorses very heartily the recommendation contained in the Report of the Special Committee on Floods and Flood Prevention, urging the establishment and unification of systematic rainfall, run-off, and flood observations covering the entire United States in far greater detail than has yet been attempted; also, the recommendation contained in the Minority Report, urging the creation of a special agency, supported by adequate appropriations, for carrying on this work. Our knowledge of floods in general is sorely in need of systematic development; the recommendations referred to indicate the first logical step to that end.

There is a crying need for carefully compiled chronological flood data showing dates of occurrence, flood heights, distribution and quantities of rainfall, rates of run-off, and notes as to what tributaries were directly responsible for the formation of flood crests, for all rivers of importance, and including also the lesser streams which, owing to geographical or commercial conditions, present special flood problems. The writer believes that the Committee can render the Profession no greater service than by outlining a plan of procedure for collecting, collating, and publishing such facts systematically.

A review of available river stage, stream flow, and rainfall data reveals a deplorable lack of accurate statistics pertaining to either floods or to extreme low-water conditions. Yet, these two subjects are of more economic importance than any others pertaining to the regimen of streams. Floods are at present attracting unusual interest; low-water stages and droughts will probably become of more and more interest as time goes on. As matters now stand, the practising engineer, who is required to study and report on means for abating flood damage in a given locality, finds three distinct classes of information at his command:

1.—River stage, stream flow, and rainfall observations, made under the direction of Federal and State bureaus, and of certain

* Dayton, Ohio.

corporations, all of which observations are more or less readily obtained in printed form. In this class belong also miscellaneous data published in technical journals. Mr. Matthes.

2.—Data pertaining to floods which antedate the periods covered by existing records, and concerning which but little has been published in technical publications.

3.—High-water marks.

Each class of data possesses limitations of its own, as will appear from the following considerations. Data of Class 1 are generally regarded as affording the most reliable information. Unfortunately, river stage records are available for comparatively few streams, and rainfall records are obtained at illogically distributed points. The average river stage record does not cover more than 20 years, a period entirely inadequate for studying floods with reference to their frequency. Even 40-year records, of which a number are in existence, are inconclusive in this respect, because they contain rarely more than one extraordinary flood. The principal short-coming of such records, however, is that they were obtained primarily to supply information of a general nature, and not to afford specific information regarding floods. This fault has been recognized, and is being remedied. The United States Geological Survey and the United States Weather Bureau, in recent years, have instructed their observers to record the maximum or crest stage of each flood, and in case of flood stages caused by back-water from ice jams, to make notes to this effect. Previous to this there was no definite practice, some observers reporting readings taken at the customary hour, others reporting the crest stage without stating in all instances the time of its passing. Others took sufficient interest to obtain a series of readings during a flood, but the Bureau, in publishing the record, contented itself with averaging them and printing the meaningless figure thus obtained as representing the average gauge height for the day. This practice is still in vogue in some quarters. Many flood heights published by the Signal Service and the Weather Bureau in their earlier reports, on investigation, have proved to be distortions caused by ice jams, and are not to be taken as indications of flood discharge. Failure on the part of engineers to investigate and check up such records before using them has resulted in the indiscriminate use of observations which are not comparable. Some engineers believe that inaccuracies and inconsistencies of the kind referred to are not likely to affect their conclusions one way or another. Others, unaware of the defects, have taken the records for gospel truth, and with painstaking care have made them the basis of mathematical and graphical studies, assigning to them a value which is wholly unwarranted.

Mr. Matthes.

There is an urgent need for a complete revision of all published river stage records and stream flow data, in so far as they relate to floods. The importance of this matter cannot be over-emphasized. A revision of this kind was undertaken some time ago by the Water Supply Commission of Pennsylvania for the streams of that State, as a result of which many of the theretofore published maximum rates of run-off have been materially increased. The writer's studies in this field lead him to believe that probably 50% of the maximum run-off figures published by various authorities, among them the much quoted ones of the late Emil Kuichling, M. Am. Soc. C. E., do not represent crest stages at all, but are based on unscientific observations of the kind just alluded to, and are not even reliable 24-hour averages. The seriousness of this state of affairs is not generally recognized, and deserves the earnest attention of the Committee.

It is generally recognized that the number of river and rainfall stations should be greatly increased. Co-operation between the Federal Government and individual States has given good results in some cases. As an instance of what may be accomplished by a State acting independently, may be cited Pennsylvania, which in 1907 took over from the U. S. Geological Survey a score of river stations, and has increased this number until at present observations are received from more than 100 stations.

The development of our knowledge of floods by continuing existing records and starting new ones is only one phase of the subject; the other phase is to gain knowledge concerning floods which took place before regular observations were begun. This involves the collecting and collating of data of Class 2.

Much valuable information concerning floods, their heights and causes, is obtainable by consulting the files of historical societies, public and private libraries, newspapers, old diaries, private records, and unpublished matter of various kinds. Extensive researches by the writer in this field have taught him that there is a vast quantity of good material awaiting him who will take the trouble to unearth it. Such material, when properly interpreted, and utilized with care, so as to eliminate erroneous data, can be made of great value, covering as it usually does the major portion of the history of any river, in point of time. Obviously, a 150-year record, consisting of fairly complete data relating to great floods, will be of much greater value in determining a future flood control policy, than a 40-year record of daily gauge heights obtained on the same stream by a $5 per month uneducated observer.

Some attempts have been made to compile flood records for a few of the more important streams of the United States, the data extending back to the earliest days of settlement. The reason more has not been

done along this line is that it has not been made anybody's business to attend to it, and because, also, of a certain amount of prejudice generally prevailing against the use of non-technical data. Federal and State bureaus have made little effort to collect information of this kind, principally for lack of appropriations, and partly because of inertia to be overcome in stepping out of the beaten paths of regular routine. The nearest approach to work of this kind was undertaken by the Water Resources Branch of the U. S. Geological Survey, when, in Water Supply Papers Nos. 96, 147, and 162, it published accounts of destructive floods during the years, 1903, 1904, and 1905, respectively, including many references to early floods. The Weather Bureau has also listed early floods for a few streams. Without doubt, both these bureaus possess a large quantity of material, which, if carefully checked and amplified, would become most valuable contributions to flood literature. In its present condition, such information lies dormant, and is of no benefit to the Profession. Mr. Matthes.

Reverting next to Class 3, High-water marks, it appears that mankind, since the earliest times, has manifested a keen interest in the destructive action of rivers. Before the days of regular observations, it had become a frequent practice to perpetuate by permanent marks the height attained by great floods. The extent to which this has been done along the streams in the early settled portions of the United States is remarkable, as will be testified to by those who have had occasion to make systematic search for such marks. Here, as elsewhere, in dealing with information pertaining to floods, it is of the utmost importance to guard against errors, and it is necessary to check the marks, not only against each other, but by comparing the information which they furnish with that obtained from accounts and other data. When made on factories, mills, pumping stations, and bridges by the mechanics, millers, or engineers thereof, such marks, as a rule, are well recorded and reliable.

The present condition of our knowledge of floods is such that few practising engineers are placed in a position where they can utilize to advantage any one of the three classes of flood data here discussed. Lack of facilities, and lack of access to old files or other sources of information stand in the way, and frequently the problem must be solved by guesswork where reliable data might have been used had they been available in conveniently accessible form. It should be made the province of Federal or State bureaus to remedy this condition. To do so calls for considerable research and academic work, neither of which should devolve on the practising engineer, or become a source of expense to his client.

In conclusion, the writer wishes to state that it is to be regretted that the duties of the Committee were limited to the investigation of flood matters only; they should have included an investigation of low-

Mr. Matthes.

water conditions. The subjects are closely related, and the methods which may be utilized for systematizing the knowledge concerning the one could without doubt be made to apply to the other. It is to be hoped that this important feature will not be overlooked when an agency is created such as suggested in the Minority Report. Such an agency could handle advantageously matters relating to low as well as to high water. Great floods have left their imprints where they may be seen for generations to come; but low-water stages have left no such records behind them. Unless an effort is made soon to trace back the happenings of this class which took place in years past, it will become increasingly difficult to glean much on this important subject.

Mr. Barrows.

H. K. BARROWS,* M. AM. SOC. C. E. (by letter).—The writer has been much interested in the report of the Special Committee on Floods and Flood Prevention, the Minority Report by Mr. Knowles submitted therewith, and the subsequent discussions by Messrs. Eakin, Hill, Leighton, Grant, and Groat.

The writer is in general accord with the suggestions made by Mr. Knowles in the way of amplifying the report of the Committee, and particularly with regard to a special National agency for making general studies of the subject of floods and flood prevention and procuring systematic and comprehensive data necessary for carrying on such studies.

Mr. Grant states the situation exactly when he says that data are not now available with which to design intelligently and economically the works to carry out the purposes contemplated by the enormous appropriations for river regulation and water conservation which have been urged continually before Congress.

The Water Resources Branch of the United States Geological Survey is the only Government Bureau carrying on systematic river measurements, and, up to the present time, its appropriation for this purpose has been very limited. The entire amount appropriated annually for gauging purposes is only $150 000, which is only partly available for river measurements and must also be used for the administrative and other expenses of this Bureau. This sum is absurdly small, and, in the writer's judgment, the Committee could well make a specific recommendation to aid in the advancement of our knowledge relative to floods and other river conditions by urging strongly upon Congress that the amount of this appropriation be increased very materially. When the great value of such data is considered from the point of view, not only of flood investigation, but of water power and water supply in general, it would seem that the annual appropriation for this purpose should be at least $500 000.

The discussion of the use of levees in flood prevention brings out clearly the fact that on large interstate streams a comprehensive

* Boston, Mass.

scheme for the entire river should be developed, as the use of levees often means a change in hydraulic gradient at flood times extending many miles up stream from the point of the works. Mr. Barrows.

Although the necessity for the use of levees in the lower Mississippi seems to have been proved, the writer is not greatly impressed by the figure of 1 365 000 000 000 cu. ft. cited by the Committee as the storage capacity of levees on the Mississippi between the mouths of the Ohio and Red Rivers. Although the figures in themselves are large, it must be kept in mind that the effect of storage capacity on a stream depends on the tributary drainage area as well as the quantity of storage. The total drainage area of the Mississippi above the Red River is about 1 259 000 sq. miles, and the 1 365 000 000 000 cu. ft. of storage capacity between levees corresponds to a little less than ½ in. in depth over this drainage area, a quantity which obviously of itself is not of great importance in retarding flood waters. Considering only the drainage area of about 329 000 sq. miles between the Ohio and Red Rivers, the storage in the levees would be only about 1.8 in. in depth over this area, or not enough to affect greatly the run-off of even this smaller district. The writer agrees with Mr. Knowles in this respect, that the potential storage over the surrounding country and overflowed land is much greater than the volume confined between levees. The important function of the levees is in increasing the carrying capacity of the channel and confining the flow, rather than in storage.

The recent report of the Miami Conservancy District is an excellent example of an intelligent solution of the flood problem on one stream wholly within one State. For the larger or more extended problems involving interstate streams, obviously, studies should be made by some National agency, and the writer believes that the Committee might well take a more positive stand on this matter and urge the creation of such an agency, supported by an adequate appropriation.

N. C. Grover,* M. Am. Soc. C. E. (by letter).—With the occupancy of the river banks and bottom lands by cities, towns, and farms, the damages caused by floods have increased, until the problem of their control has become of National importance. Recent disastrous floods have led to the appointment of municipal, State, and Federal commissions for the study of local conditions or special phases of the flood problem. The appointment of a Special Committee of the American Society of Civil Engineers for study and report on floods and their prevention is a manifestation of the interest in and importance of the problem. Mr. Grover.

The duty of the Society to make a broad, comprehensive, and unbiased study of the flood situation having been recognized by the

* Washington, D. C.

Mr. Grover.

appointment of this Committee, a heavy burden of responsibility rests on the membership in its attempt to guide the various governmental organizations to an adequate solution of the flood problems. The Society must now see to it that this responsibility is discharged properly and adequately, and its final action should be sound in principle, broad in scope, and definite in application, so that it may serve as a basis for safe, adequate, and unbiased legislation.

At the present time flood work is scattered through many organizations. Several States and municipalities have investigated local flood problems. The United States Weather Bureau has developed an efficient service for flood warnings on the principal rivers of the country, and has collected many valuable records of river stage. The United States Geological Survey has collected many records of flood discharge, as a part of its work in systematic stream gauging, and has made topographic maps of river basins and of reservoir sites that are invaluable in a study of floods and their control. The Corps of Engineers, United States Army, has charge of all construction on navigable streams, and, incidentally, has collected much information relative to floods on such streams. Each of these various organizations has conducted its work in full recognition of the work of the others, but with little actual co-operation. There has been, however, no organization to undertake a broad, comprehensive study of the whole problem.

Flood problems range in complexity and importance from those surrounding a local flood affecting only a small area in a single State to those involving the welfare of the people of several States, or even important international questions. Present methods of treatment are almost invariably local and piecemeal, without proper consideration of the general situation, of possible antagonistic results of different projects and methods, or of the possibility of disastrous effects of projects on unimproved parts of the river system. They do not bring about, therefore, that general orderly improvement in the condition of river stage and erosion that should result from correct and adequate methods of treatment. The co-ordination of projects according to sound and harmonious methods should also eliminate useless efforts and waste, and secure the desired results at a minimum cost.

The elements of a general programme for flood control, on which recommendations should be made in the report of the Society, are:

1.—The development by appropriate research of a fuller knowledge of the laws of river hydraulics and physiographic processes which is prerequisite to a sound practice of river control;

2.—The expansion and improvement of methods of control, on the basis of fuller scientific knowledge, including, possibly, vertical as well as horizontal control of streams, with con-

sequent reduction of necessary levee heights, contraction of levee systems, and elimination of harmful reactions between different projects and methods;

3.—The co-ordination and standardization of the collection of data as to quantity of water, débris in transit, and consequent adjustment of grades and channel forms;

4.—Surveys necessary as a basis for the design of regulatory works, estimates of cost, and of the effects of such works;

5.—Agencies to be used in collecting data and in building and operating the necessary structures;

6.—Division of cost of such structures among the organizations co-operating, or the parties benefited;

7.—Possible combination of flood control, navigation, water power, drainage, and irrigation, under the same general regulative programme;

8.—The organization of a special Federal bureau equipped to execute a full programme of river improvement.

The Report of the majority of the Special Committee on Floods and Flood Prevention, which was presented at the Annual Meeting, was discussed by the minority as a Progress Report. The Chairman, later, requested that the report be considered as the Final Report of the Committee. It is unsatisfactory to the writer, however, either as a progress or a final report, largely because of its apparent lack of clear insight into several important phases of the flood question and of definite suggestions or recommendations. It calls attention only to the need for additional and standardized physical data, and discusses certain suggested methods of flood control in a manner that favors those now in vogue. It ignores the necessity for developing a science of river hydraulics and improving the practice of river control, for active co-operation of agencies in collecting data, in building and operating structures, and in dividing costs, and for the co-ordination of all flood work under one directing head and in one programme. The Minority Report is a great improvement on that of the majority, in many respects, but does not accomplish the purposes, as they appear to the writer, of a final report of a committee of this Society.

It is believed, therefore, that both the Majority and Minority Reports should be received, the Committee discharged, and a new committee appointed to consider again the important problems involved, in the hope that a more comprehensive and definite report may serve as a basis for the final action of this Society on the important problems involved in the flood situation.

Mr. La Rue.

E. C. La Rue,* Assoc. M. Am. Soc. C. E. (by letter).—The Committee has wisely called attention to the paucity of data available for studies of flood control, but it does not seem consistent in the same report to draw definite conclusions with respect to the relative merits of the various methods of flood control and flood prevention. The writer agrees with the statement of Mr. Knowles, on page 1230, that the Committee has given a single view "on controversial subjects on which it must be recognized that much more information can and should be obtained".

For example, on page 1228, the Committee says:

"As you proceed down stream the influence of reservoirs on flood prevention rapidly diminishes, and the influence of levees correspondingly increases in importance as a method of flood protection. On the lower alluvial reaches of long rivers, such as the Mississippi and Colorado, they afford the only sure means of flood control."

This statement is not correct when applied to the Colorado River. The writer has recently completed a report, entitled, "The Colorado River and its Utilization",† in which it is shown that reservoirs may prove an effective means of preventing floods on the lower Colorado. The area of the Colorado River Basin is 244 000 sq. miles. The precipitation and run-off from the lower half of the basin is small compared with that on the upper half. At Yuma, Ariz., 92% of the annual run-off is contributed by that part of the drainage basin lying above the Utah-Arizona line, which is 700 miles above Yuma. Green and Grand Rivers, which unite to form the Colorado in southeastern Utah, drain 70 300 sq. miles, which is only 28.8% of the Colorado River Basin; yet these rivers contribute 76% of the water that passes Yuma. A dam constructed to raise the water level 270 ft., immediately below the junction of Green and Grand Rivers, would create a reservoir having a storage capacity of 8 600 000 acre-ft. On June 14th, 1914, a maximum flood of 137 000 sec-ft. occurred at Yuma. The crest of this flood at the junction of Green and Grand Rivers was 120 000 sec-ft., and passed that point on June 3d. By utilizing the reservoir site at the junction of the Green and Grand, this flood of 137 000 sec-ft. at Yuma could have been reduced to 17 000 sec-ft. This reservoir site is 880 miles by river above Yuma, and about 1 000 miles above the mouth of the Colorado. It is clear, therefore, that in this basin, at least, the influence of reservoirs on flood prevention does not rapidly diminish down stream. The Colorado tends to overflow its banks in the vicinity of Yuma at the 25-ft. stage on the gauge. The average carrying capacity of the channel at the 25-ft. stage is about 50 000 sec-ft. The writer, therefore, believes that nearly all

* Salt Lake City, Utah.

† U. S. Geol. Survey, Water-Supply Paper 395.

overflow can be prevented on the lower Colorado, and that the flow can be regulated to meet the demand for water for irrigation, if the reservoir site at the junction of Green and Grand Rivers is utilized, and detention basins and reservoirs are constructed on the San Juan and Gila Rivers for the purpose of reducing the violent floods that happen occasionally on these tributaries. On the lower reaches of the Colorado the river bed is being slowly built up, and at the present time the river is flowing on the highest ridge of its delta. When the flow of the Colorado is regulated, the cost of constructing levees and bank revetments will be reduced to a minimum. It is probable, therefore, that the final plan for the control and prevention of floods on the Colorado will involve the construction of reservoirs, detention basins, and levees. Mr. La Rue.

As to the proper methods of controlling and preventing floods, there are nearly as many opinions as there are engineers engaged in the study of the problem. Each drainage basin or river system presents a different problem, and perhaps this fact accounts for the divergence in the opinions expressed by engineers as to the effectiveness of the respective methods of flood control and flood prevention. The opinion of each engineer will probably be influenced largely by conditions in drainage basins with which he is familiar.

The Committee, no doubt, did not intend its report to be interpreted as an invitation to engineers to discuss the relative merits of reservoirs *versus* levees as a means of flood control, but the discussions that have been published indicate a tendency in this direction. To the writer it seems no more consistent for engineers to discuss the relative merits of the various methods of flood control without confining their discussions to conditions in a particular basin than it would be for two engineers to debate the applicability of the Cippoletti weir *versus* the current meter as a means of measuring water, without agreement as to the quantity of water to be measured and the conditions controlling such measurement. One engineer, having in mind the measurement of streams in which the maximum discharge does not exceed 10 sec-ft., might advocate the use of the Cippoletti weir; the other, having in mind the measurement of the flow of the Mississippi at New Orleans, might as strongly advocate the use of the current meter.

When adequate data are obtained, reports will be prepared presenting plans for the control of floods in particular drainage basins. Discussion of such reports will be of great value, in that it will concentrate the attention of engineers on specific problems. With this concentration of effort, in solving one problem at a time with but one set of conditions, no doubt most engineers will come to agreement, and possibly all will agree that under certain conditions a reservoir

Mr. La Rue.

may serve more than one purpose; that in some drainage areas detention basins will solve the problem; that in others reservoirs must be constructed; and that on long rivers it may be necessary to construct check dams, detention basins, reservoirs, and levees.

So far as the problem of flood control and flood prevention is concerned, it would seem that the most valuable service that can be performed by the Engineering Profession at present is that of urging (page 1234) the establishment of a "special agency, supported by adequate appropriations, for the purpose of studying stream regulation in its largest sense, and under whose direction all data shall be collated, according to uniform standards and systems, so that appropriate development of the science shall be made".

Mr. Gannett.

FARLEY GANNETT,* ASSOC. M. AM. SOC. C. E.† (by letter).—After reading the report of the Special Committee on Floods and Flood Prevention, the thought presents itself: "What is to be done next"? It was hoped that the Committee would indicate a definite course of procedure to be followed in order to accomplish the gradual reduction of the flood hazard, but it seems that it has not done this. Some members of the Society doubtless expected to find in the report tables showing the magnitude and frequency of floods, together with flood damage estimates, and other information, but it is thought the Committee was wise in not publishing these data. Such data are most useful and necessary to accomplish the control of floods, and their wide distribution would facilitate the intelligent construction of such works, but, without a bountiful appropriation, the Committee could not have been expected to collect, correct, arrange, and tabulate the vast store of records which it could have found available. A list of references to published sources of flood information, however, would have been a useful addition.

Flood data should be collected, studied, analyzed, revised, and made available to the Profession; and would not such work be a proper avenue for the expenditure of the funds of the Society? Certain States are undertaking to do this; the United States Government, in several different Bureaus, is doing some work along these lines; individual engineers have done a great deal, but they have not the resources in time or money to treat the data in the proper way; and, therefore, it seems that, if this information is to be placed at the disposal of the Profession, the American Society of Civil Engineers is the proper organization to do it, even though it may cost many thousands of dollars. It is recognized that there are other fields which probably deserve equal attention by the Society, and that all desirable fields cannot be covered simultaneously, but is there a reason for doing nothing simply because all cannot be done at once?

* Harrisburg, Pa.

† Now a Member.

Mr. Gannett

The Flood Committee might have been expected to publish flood height and damage data or to recommend concurrent State and National legislation which would tend toward reducing the flood hazard. The latter is believed to be by far the more important. It is one thing, however, to recommend remedial legislation and another thing to have it adopted, and that is where the real work would come.

Channel Reduction by Encroachments.—The writer must disagree with the Committee in its statement that "the obstruction of the flood plain by the works of man has in many cases largely increased flood heights for the same volume of discharge". In this discussion we are dealing with great and damaging floods on large streams, and, as a result of an intensive study of past floods and experience in passing upon proposed encroachments in stream channels, in enforcing the laws of the State of Pennsylvania in this respect, the writer thinks that, except for small floods which are confined within well-defined channels, river bank encroachments, and obstructions, have, with but a few exceptions in Pennsylvania, had small effect on flood heights. When floods are confined to channels between normal banks, their height is raised by bank extensions, bridge piers, buildings, foundations, etc., but great floods, in Pennsylvania at least, almost everywhere leave the well-defined channel and inundate the whole valley from hill to hill. During such floods, which overtop the river banks, the extension of such banks makes little or no difference in the gauge height attained.

With small streams the statement of the Committee applies more truly, however, because railroad embankments, highways, etc., crossing such streams over culverts of insufficient capacity, with long, high approach fills, often retard the flow and back up the water to damaging heights. When such accumulations of water finally overtop the embankments and cut them away, the damage and stage below are often far increased.

On Mill Creek, at Erie, Pa., with a tributary water-shed of 13 sq. miles, $2 000 000 damage was done by a flood on August 3d, 1915. This was the third great flood during the last 40 years, each doing vastly more damage than the one previous, not so much because there was more water, but because each time there was vastly more property, in houses, stores, and factories, to be damaged, and also because inadequate culverts carrying streets over the creek, with approach fills, became clogged, backed up the water, were overtopped, and the approaches cut away, to disgorge the accumulated water down to the next culvert, where the process was repeated.

One of the greatest obstructions which can be placed in a big river, as far as impeding the area is concerned, is a masonry arch bridge. Yet when the Cumberland Valley Railroad Company asked

Mr. Gannett.

permission to place such a structure nearly a mile long over the Susquehanna River at Harrisburg, it was found that its effect on an estimated maximum flood of 900 000 sec-ft. (previous actual maximum flood 700 000 sec-ft.) would be to raise it 0.9 ft. over what it would be without a bridge.

Encroachments, however, are going on in every place where no control over them is being exercised; and, if permitted to continue, will in time become of consequence. Heretofore, except at a certain limited number of places (considering only large streams), they have not become of damaging dimensions, but, as every little bit tends in the wrong direction, all encroachments which would tend to restrict flood discharge below safe limits should be prohibited. Few States have legislation on this subject. Until recently, the National law regarding the building of structures in navigable rivers was not enforced from this point of view. The length of rivers classed as navigable is so great, and the corps of engineers available to the War Department to enforce this law is so small, that an attempt to carry out its provisions is only made at certain points.

Pennsylvania has had a good law, well enforced, for 9 years, controlling encroachments along, or obstructions in, stream channels, and a vast benefit has resulted, not so much in bettering previously existing conditions as in preventing worse conditions from arising; and improvements over previous conditions have been obtained at many points. This law prevents the dumping of wastes of all kinds over river banks, unless the slopes are protected, and thus tends to reduce silt carriage by the streams, to be deposited lower down. None of the neighboring States has such laws, and there is nothing to protect Pennsylvania from receiving in its rivers the washings of refuse from banks in States up stream.

Such a law, enacted by all States, modified as necessary to meet local conditions, is a prime requisite and a most proper recommendation for the Flood Committee to make, in order to preserve the streams as they are, prevent them from getting worse, as far as channel capacity is concerned, and to effect a measure of improvement whenever opportunity offers.

The Popular Fear of Dams.—Another thing which the Society can do to further flood control is to assist in disabusing the public mind of the idea that a dam is a dangerous structure. As a result of several disastrous dam failures, two of them in Pennsylvania, the public has the idea that a dam is bound to be a grave source of danger, and the location of such a structure above a city a menace. The broadest schemes of flood control cannot be developed unless this feeling is removed, and it can only be removed by a concerted campaign of publicity such as could and should be carried on by the American Society of Civil Engineers.

Mr. Gannett.

Surveys and estimates at Erie showed that the most satisfactory as well as the most economical method of controlling floods in Mill Creek was by the construction of a detention reservoir and a conduit 18 ft. wide; but, on account of the feeling in Erie against a dam of any kind, and of the necessity of going before the people with a bond issue election for funds with which to construct the flood control works, it was decided to adopt an alternative plan of a much larger conduit and omit the dam entirely, at an added cost of more than $100 000. It was believed by the City Commission that if a plan involving a dam was submitted to the voters the bond issue would fail. Without the dam, the bond issue of $950 000 carried by a five to one vote. The City Commission of five members was unanimously in favor of the plan involving a dam, as opportunity was afforded to convince them of its advantages by frequent discussions; but such methods could not be applied to the entire population in the short time available. Therefore the furtherance of a propaganda favorable to dams, and the spreading of the conviction that dams are not dangerous, would be an important function which the Society could assume in furthering flood control.

Multiple Use of Reservoirs.—The writer believes, with Gen. Chittenden, that reservoirs may be utilized satisfactorily for flood control and other purposes as well. He had occasion to work out this problem on two large storage projects, and in one of these cases it was thoroughly proved that a reservoir, designed primarily for increasing the dry-weather flow for industrial use, would reduce floods in the congested section of the river below, by 30% in height, and would practically eliminate damage. In the other, by raising a proposed masonry dam for water power a very few feet, almost complete control of floods on a water-shed of 1 200 sq. miles, would be effected. In the former case, the reservoir is long, wide, and shallow, covering 30 sq. miles, on a water-shed of 150 sq. miles. The absorption of flood flow by this reservoir would be enormous, a 3-ft. rise absorbing an 8-in. rainfall on the water-shed. The freeboard on the dam is 10 ft. In the latter case, the dam is about 260 ft. high, and the reservoir more than 40 miles long. The capacity curve of this reservoir is such that a few feet on top gives capacity equal to a large percentage of the volume below the level required for water power.

With few exceptions, storage in the upper part of a reservoir is the cheapest, so that, by increasing the height of dams erected for other purposes to a height greater than necessary for that primary purpose, the necessary storage for flood absorption will be obtained at more reasonable cost than if a dam or reservoir is built only for flood control.

Mr. Gannett.

Several of the European nations have in this way created effective control and utilization of important streams. Thus, storage developments on the Oder River, in Silesia, has effected flood protection in the valley below and has also permitted the generation of several thousand horse-power; storage for navigation improvements on the River Rhône has reduced flood heights below storage reservoirs constructed with both ends in view.

Floods come so seldom, strike at such widely different parts of the land, and at such varied seasons, that in the popular mind they have come to be accepted as acts of Providence. This superstition is being gradually eliminated, but the feeling is still prevalent that floods, like lightning, never strike twice in the same place, and so there is no use trying to do anything about it. Furthermore, the writer thinks most engineers will agree that it is impossible to construct flood control measures, where a likelihood exists, if a damaging flood has not occurred, that the financial and governing bodies will refuse to "lock the barn door before the horse is stolen," even though one can show the presence of thieves in the vicinity and the absence of locks on the doors. Flood protection or control measures are usually very costly, and floods seldom recur in any one place, and it is impossible to prophesy how soon the next one will come, so that it is impossible to determine exactly the amount of money which can be expended economically for such works. Again, it is usually necessary in large flood control projects to obtain the co-operation of corporations, cities, counties, States, and the Federal Government, or several of them. All these conditions, as well as numerous others, make the final accomplishment of water storage measures, for flood control alone, a long and laborious undertaking, so long that often the necessity therefor and the losses and horrors of the last flood have been measurably forgotten before all these steps can be accomplished, and the project fails.

For these reasons the writer believes that real widespread flood control through reservoir construction and storage will be brought about by the construction of reservoirs principally for other utilization purposes, such as water supply, water power, industrial use, navigation, irrigation, and for esthetic purposes, such as park lakes, improvement, sanitation, etc.

Our existing State laws, under which most works of this kind would be and are built, will have to be amended in most States to provide a means by which such multiple use may be made of reservoirs through the division of cost between, for example, a corporation building a water-power reservoir and a city desiring flood control, or between one city desiring water supply and another requiring flood control, etc.

Mr. Gannett.

Such legislation has been suggested for Pennsylvania, but has not yet been placed on the statute books. Projects involving several hundred thousand continuous horse-power are now chartered by this State, but remain unbuilt, because of the lack of definite and favorable water-power laws under which they may be built and operated. Others are too costly, as water-power projects alone, to warrant construction in this State, the home of coal. With favorable water-power laws, and with the right to co-operate with municipalities, counties, and the State, many hundreds of thousands of horse-power, now going to waste, would be developed; many towns and cities would have reduced flood hazards, navigation on several large rivers would be improved, and sanitary conditions along the water-fronts of many river communities would be greatly benefited.

Thus another line of legislative enactment, essential to the promulgation of flood control, is the passage of laws permitting and facilitating the generous development of water supply, water power, and irrigation projects, and the division of the cost of constructing and operating them between corporations desiring such works for financial return, and municipalities, counties, States, and the Federal Government desiring them for flood control and navigation.

The Water Supply Commission of Pennsylvania approved of the incorporation of a large water-power project in the western part of the State, involving the construction of large storage reservoirs and the installation of 200 000 h. p., on condition that the operation of the main storage reservoir be subject to the direction of the Commission, as respects maintaining a certain dry-weather flow below it, and as respects absorbing floods.

Forests.—The writer thoroughly agrees with Gen. Chittenden in his contention that, though forests may and probably do mitigate ordinary floods to a certain extent, they do not affect the volume of discharge in great floods. Anything but circumstantial and theoretical evidence on this point is impossible to obtain. The studies which were made of Pennsylvania river floods showed that whenever we could go back 75 or 100 years, substantial and reliable records of floods were often found exceeding anything in more recent years, since the forests were largely removed. This was clearly shown by finding accurate records of two floods at Pittsburgh, in 1762 and 1763, considerably exceeding that of 1907. Also by finding records of a flood on the Susquehanna River at Wilkes-Barre, in 1865, exceeding that of 1902 by several feet in height, and floods in 1784 and 1807 nearly as great. A flood in the Schuylkill River in 1850 exceeded that of 1902 materially. These facts prove nothing, but they show that the dense forest growth, which covered the State at the earlier dates, did not prevent great floods, which, if they occurred to-day, would be truly disastrous.

Mr. Gannett.

Detention Reservoirs.—The writer cannot but feel that on large streams, where water power might be obtained, or where navigation improvement might be gained by storage, detention reservoirs are an economic waste. It is unfortunate that the greatest and most spectacular flood control project of our time, the Dayton project, is planned on that principle. The conditions there apparently made that the only plan that could be adopted, just as at Erie, conditions made the plan without a dam the only one that could be put through. The Erie case also is unfortunate, but being smaller, the failure to utilize the best and most economical method is not so harmful, as it is not so widely known and will not be pointed to so frequently as a precedent as will the Dayton project. The failure to utilize the power of the Scioto River and its tributaries, which, with permanent reservoirs of greater capacity, might have been made available, will set a precedent which will undoubtedly lead to the utilization of this plan elsewhere, where the conditions are not the same and where complete utilization and conservation would have been practicable.

Flood Warning.—The worst feature of floods is the damage they do to life and property. There are two ways of reducing this damage, one is to control the floods and lessen their height, and the other is to get out of the way of them and remove perishable property to places above flood height. The first proposition has been much discussed, but the latter, it seems, has not received the attention it deserves. This involves flood warnings. By timely warnings many lives can be saved and much valuable, perishable property can be removed beyond the danger zone. Until the far-distant day when flood control is general, more attention should be devoted to early and accurate flood warnings.

The Federal Government maintains a flood warning service which has proved itself of great value. It is a Herculean task, however, to send flood warnings over this vast land of ours, and the means at the disposal of this bureau have confined its work to certain points and a limited number of streams.

Following the flood of March, 1913, which visited streams in Western Pennsylvania, a law was enacted, and $10 000 was appropriated by the State Legislature, with which to give to the people a more intensified flood warning service than was possible by the United States Government. This law was drafted with the approval of a United States Weather Bureau representative, and in the 3 years during which it has been enforced by the Water Supply Commission, a great quantity of property has been saved from damage. A larger appropriation would make greater savings possible. In Pennsylvania, however, this service is hampered by the lack of similar service on the head-waters of the Susquehanna, Allegheny, and Delaware Rivers,

which rise in New York and pass through or along the border of Pennsylvania for hundreds of miles. Mr. Gannett.

Either by vastly increasing the resources of the United States Weather Bureau for flood warnings, so that it could give attention to other than the few great rivers of the country, or by adopting uniform flood warning legislation in the several States, much loss in life and property could be prevented while we are waiting for control works to be built.

An important duty of such a service is also that of warning prospective constructors of railroads, highways, bridges, factories, mills, and dwellings of the limits of the flood zones of rivers, so that they may not locate within such area, or if they do, that the building site may be elevated above flood level. If there were such an organization in each State, under State or Federal control, and the people knew of its existence, as they would if proper publicity was given to it and its work, then it would be possible to reduce greatly the increase in the damageable property which is constantly being placed in the way of floods.

In conclusion the writer would suggest that it is the province of this Society to do three things:

1.—Place at the disposal of its members full and accurate flood data;

2.—Change the popular fear of dams into an understanding of their security;

3.—Formulate and push through the adoption of legislation along these lines:

A.—To control obstructions and encroachments in or along streams;

B.—To permit of co-operation between corporations, States, municipalities, and the Federal Government in the construction and operation of storage reservoirs for water power, water supply, and other commercial uses, so as to adapt them for flood control as well;

C.—To extend the Federal, or establish a State, flood warning service.

C. E. GRUNSKY,* M. AM. SOC. C. E. (by letter).—The discussion which the Committee's report has provoked is of a character fully justifying the report, notwithstanding the fact that the Committee was not in a position to attempt to say the last word on the subject of flood control. Mr. Grunsky.

Some of the statements made by those who point out the incompleteness of the report merit reply, in order that wrong impres-

* San Francisco, Cal.

Mr. Grunsky.

sions may be corrected. Mr. Eakin says: "It is indirectly stated that the use of levees effects an increased channel storage that induces a lowering of flood levels." No one who knows anything about the propagation of a flood wave could by any possibility intentionally make the statement that the reduction of the flooded area which results from the construction of levees will reduce the elevation to which water will thereafter rise between the levees. The language used by the Committee (of which the writer was a member) is therefore unfortunate. The levees are put on the banks of rivers for the purpose of confining the water to a restricted channel and thereby increasing the rate of flow in this channel, and this cannot be done without causing the water between the levees and within the channel to rise to greater height than that which would have been attained without levees. It takes the crest of a flood wave 10 days, or about that time, to travel in the Mississippi River from Cairo to New Orleans. Let it be assumed that at flood the volume of flow is such that levees confine the water to the river and to bank-land areas between the levees. It is evident that in such a case the discharge of the river in excess of ordinary flow for about 10 days before the cresting of the flood at New Orleans has been consumed in filling the river channel above that point from a low to a high stage. It is also evident that this channel storage is greater than it would have been if there had been no levees. To the extent that this increase of channel storage is made possible by the levees it is a factor making for a reduction of the maximum flow at all down-stream points.*

Channel storage between levees does not reduce the total run-off, and it does not reduce the water surface elevation of the river at flood, unless this be in the exceptional case of scour, which may result from the higher velocities in the channel between levees than existed under natural conditions. No claim can be made, and none was intended to be made by the Committee, that the confinement of water by levees will decrease the original maximum stream flow at the mouth of the river. Levees are built for the purpose of reducing flooded areas. They are built to keep water away from land that without them would be less desirable for agricultural, industrial, and other uses. Consequently, for the same volume of flood flow, the opportunity for storage, taking the river basin in its entirety, is less after levees are built than before. The flood wave reaches the mouth of the leveed river with less elongation than under natural conditions, and consequently the discharge at the peak must be greater. As an illustration, the Sacramento Flood Control project may be referred to. Under natural conditions the floods of Sacramento River inundated broad lateral basins, and the lower reaches of the river had a maximum

* See *Transactions*, Am. Soc. C. E., Vol. LXI, p. 332; and also Report of Commissioner of Public Works of California, 1895, p. 130.

flow of about 200 000 sec-ft. The withdrawal from inundation of the islands of the delta region of this river and of the various flood-basins which border the river will increase the momentary flood maximum to more than 500 000 sec-ft. Of this quantity, in the latitude of Sacramento, it is proposed to hold as much as possible in the river, 20 to 30%, confined between levees of reasonable height, but at elevations which at extreme flood will be about 7 ft. higher than the original river flood-plain. It is the additional channel storage represented by this added depth of water which the Committee had in mind when it referred to "the resultant reduction of flood height." What the Committee desired to do was to call attention to the added storage as a factor making for elongation of the flood wave and consequent reduction of maximum discharge, without any intention of claiming that channel flood heights as originally existing would be reduced by the construction of levees. Mr. Grunsky.

In connection with this matter, and in reply to the remarks of Gen. Chittenden, the general principle should be kept in mind that the elongation of a flood wave as it passes down stream is due to the effect of storage. If there were no change possible in the volume of water in storage between an up-stream and a down-stream point, as in the case of a closed conduit, there could be no elongation of the flood wave. The accession of water at the upper point would at once be manifest by an increased discharge in equal quantity at the lower point. Storage, whether in the channel or in overflow basins, has the effect of elongating in some measure every flood wave that travels down a river, and by such elongation the time of passage is increased and the flow at the peak is correspondingly reduced. It follows, as demonstrated by the writer in a paper prepared in 1880 while he was Assistant State Engineer of California, and published in 1895 in the Report of the Commissioner of Public Works of California,* that the maximum discharge of a river which receives no accessions from tributaries will decrease with distance down stream. Every decrease of available storage space, such as may result from a contraction of the waterway, will reduce the effect of storage and will tend to increase the maximum discharge at down-stream points. Every increase of storage space, resulting from the raising of levees or the adding of retention reservoirs, on the other hand, will decrease the maximum flow at down-stream points.

The Committee shares the view expressed by Mr. Eakin when he says:

"No individual or organization has as yet commanded such proficiency in all these sciences as to enable them to outline a programme of river treatment with dependable authority."

* See also *Transactions*, Am. Soc. C. E., Vol. LXI, p. 332.

Mr. Grunsky.

Herein lies the justification of the Committee in presenting a report in which the shortcomings were known to the members, and which was not put forward as exhaustive on the subject of flood control, a subject which necessarily presents as many different aspects as there are river systems.

It happens frequently, as in the case of the Sacramento and San Joaquin Rivers, in California, that some of the natural flood basins along these streams, such as Butte Basin to the northward of the Marysville Buttes, Upper Colusa Basin on the west side of Sacramento River, and, to a lesser extent, Sutter Basin, Lower Colusa Basin, and American Basin, and some of the submersible lands along the San Joaquin River, partake of the nature of the lands which in connection with flood-control projects on other river systems are selected for detention reservoirs. The demand is strong in the California case for the protection of these submersible valley lands against overflow. It becomes an economic question, then, to determine where the line should be drawn, and it is by no means certain that complete protection against floods is in all cases justified. Occasionally, it will be found advisable to retain a natural overflow basin, not only for the control of the floods which it helps to effect, but also as a recipient of some of the silt carried by the stream. The permanent utilization of a natural flood basin seems particularly desirable when the basin is situated so that, while acting as a detention reservoir, it can be drained of its water in time to leave the land available for the cultivation of summer crops. In 1850 the United States gave to Arkansas and a number of other States, for the purpose of reclamation, the land which was segregated as swamp and overflow, and these several States thereupon proceeded to divest themselves of ownership as rapidly as possible. They blundered. The land subject to inundation should have remained in public ownership until comprehensive plans for flood control were made. It would then have been a simple matter to have the plans carried out in proper sequence, and much embarrassment would have been avoided that now results from the demand that protection be provided for lands which, if they were not in private ownership, would to no inconsiderable extent be put in a class requiring only partial protection or fair protection against ordinary and not extraordinary floods.

Mr. Hill points out that the extreme floods of recent years are not due to changed climatic or physical conditions. The example which he supplies of an extreme flood stage in the Great Miami in 1805 before forests had been removed suggests that it would not be out of place to refer to some additional facts to show that a connection between deforestation and stream flow will remain difficult to establish.

Mr. Grunsky.

The writer, in a paper presented to the Society some years ago,* has shown that the dominating cause of changes in the surface elevation of the Great Lakes is the climate, and that a long period of less than normal rain and snow may be followed by another with more than the normal. A still better example to illustrate the variation in the rainfall and run-off is the Great Salt Lake. This lake was very low when visited and sounded by Capt. Stansbury in 1849. It was low when visited by Fremont some years earlier. In the years preceding 1869 it rose, ultimately reaching an elevation about 11 ft. above that of 1849, and then, with numerous minor fluctuations, decreased in extent and in elevation until 1906, when its water surface was about 4 ft. lower than it had been in 1849. It was supposed by many that, on account of the increasing utilization of water for irrigation on its water-shed, the lake would never again rise to anywhere near the high stages of 1868 to 1876, but this view was in error. The lake is now about 8 ft. higher than it was at its lowest stage in 1904, having maintained this high stage for several years. For a long time preceding the low period of 1849, and extending to about 1861, the rainfall in the region tributary to Salt Lake as a water-shed must have been less than normal. Then followed a number of years in which, taken collectively, there was more than normal rain, until about 1876, after which there came another period with less than normal rain as the average for a number of seasons. The consequent decrease of run-off and the increasing use of water for irrigation brought the lake to its lowest stage in 1906. In the case of this lake, which has no outlet, the rise and fall is a fairly good index of the run-off, and therefore of the rainfall, when groups of consecutive years are considered. The problem, moreover, is not here complicated by deforestation. It appears from this and numerous similar cases that very large variation in the seasonal water production of any region may be anticipated, and that the persistence of any tendency which the seasonal run-off may have to increase or decrease for a number of years is not to be accepted as conclusively demonstrating either a permanent change of climate, nor yet that such increase or decrease is in any way related to aforestation or to deforestation of water-shed areas. The same general statement will apply also to the possible momentary maximum stream-flow. The factors affecting the rate of run-off are, moreover, so many and so inter-related that it will remain difficult if not impossible to make a conclusive determination of the effect of forest growth on flood discharge.

Mr. Leighton is evidently of the opinion that no report on the subject of flood control can be a well-considered report which does not

* *Transactions*, Am. Soc. C. E., Vol. LXIII, p. 31.

Mr. Grunsky.

recognize the forest as one of the material factors which influence the magnitude and frequency of floods. Much as the writer has studied this subject, he has yet to find any convincing demonstration that there is such an effect. Generally, the individual cases cited are so complicated by related circumstances that the evidence is not conclusive. The writer is not prepared to accept, and does not believe that the Profession will accept, as final, any mathematical demonstration that forest growth will markedly reduce or meliorate flood conditions. If the statement made by the Committee gives the impression that the quantitative influence of the forest on the frequency and magnitude of floods is not proved, this is exactly what one member of the Committee, at least, intended. This is without prejudice to the forest, which the writer would like to see extended and maintained to meet fully at all times the requirements of the country. The writer, moreover, does not wish to be classed among those who will not concede that it may yet be possible to demonstrate the true relation of the forest to the flood; and, for that reason, he subscribed to the statement in the report that the exclusion of the forest as a method of flood prevention had not yet been demonstrated, though he believes that, except in the rarest cases, conditions will never be such that the forest will become a material factor.

The maximum stream flow is not dependent solely on the rainfall and the rate at which snow is melting; it depends also on the condition of the surface of the ground on which the snow lies or the rain falls. Usually, the period of intense rain which produces flood stages is preceded by rain which saturates more or less thoroughly the top layers of the soil. This is least likely to occur in sandy and gravelly regions and where loamy soils are well tilled and are deep. It is most likely to occur in regions where the ground is swampy and naturally full of water, or where the flood-producing rain falls on frozen ground which requires but little water for complete saturation. It follows that, whenever a region which in its natural condition was swamp has been made arable and brought under cultivation, the probability of complete saturation preceding a flood-producing rain will have been reduced, and some effect on the frequency and intensity of the flood condition in such a region will have to be conceded to the reclamation work. The main effect of any such modification of surface conditions should be sought in terms of water storage and retardation of the flood wave, because, if thereby the resultant elongation of the flood wave can be determined, some basis will exist for estimating the quantitative effect on the maximum flow. The writer agrees with the comments of Gen. Chittenden in this regard, and shares his view that the modification of the effect of soil cover and absorption by Man's occupancy and use of the soil will be a negligible factor in the excessive rainfalls which produce great floods.

Mr. Grunsky.

In the light of present information, the writer agrees too with Gen. Chittenden when, after referring to the aggravation of flood damage which results from the obstruction and use by Man of Nature's overflow channels, he says:

"The foregoing remarks disclose the reason why flood destructiveness is increasing. It is not because floods themselves are increasing, either in frequency or intensity, but because property subject to destruction is very greatly increasing, and as yet protective work does not keep pace with this increase."

The writer, though having qualifiedly subscribed to the Committee report, is not in full accord with its reference to outlets. Concentration of the flood flow in one channel is desirable. Separation into a number of channels is undesirable. The conditions, however, are not always such that a single channel can be given adequate capacity to carry all the water presented at flood. The study of the question what to do when this is the case led the writer to formulate certain principles for the treatment of Sacramento River floods,* substantially as follows:

First.—Make the river carry as much water as possible between levees of reasonable height.

Second.—Let the flood-water in excess of capacity between levees go out of the channel at selected points under control.

Third.—Confine the outgoing surplus waters to limited areas, and keep them under control until they may re-enter the river or can be delivered into the bay.

The writer has not modified his views in this respect, having, subject to these principles, always been in favor of relief weirs or controlled outlets. These are not to be confounded with ordinary outlets which begin to function before the river has reached the danger line and which become secondary branches of the stream. It is outlets of the latter kind, in the sense of a division of the stream, which with good reason are disapproved by the Committee.

The writer is pleased to find Gen. Chittenden in accord with the writer's view that the cut-off is generally a desirable improvement, and that the fear that shortening a river channel will interfere with its usefulness as a commercial highway is not ordinarily well grounded. The sketch, Fig. 5, is from an old document, and shows the extent to which, by intelligent direction and restraint, the course of the Rhine in the vicinity of Germersheim was modified during the period from 1817 to 1861. This sketch shows channel shortening and alignment modification quite comparable to that which might be carried out on the Mississippi, on the Missouri, or on the Colorado, if the necessary outlay, including permanent bank revetment, were justified, and the occupancy and use of the bank-lands do not already set a

* Report of Commissioner of Public Works of California, 1894–95, p. 59.

Mr. Grunsky.

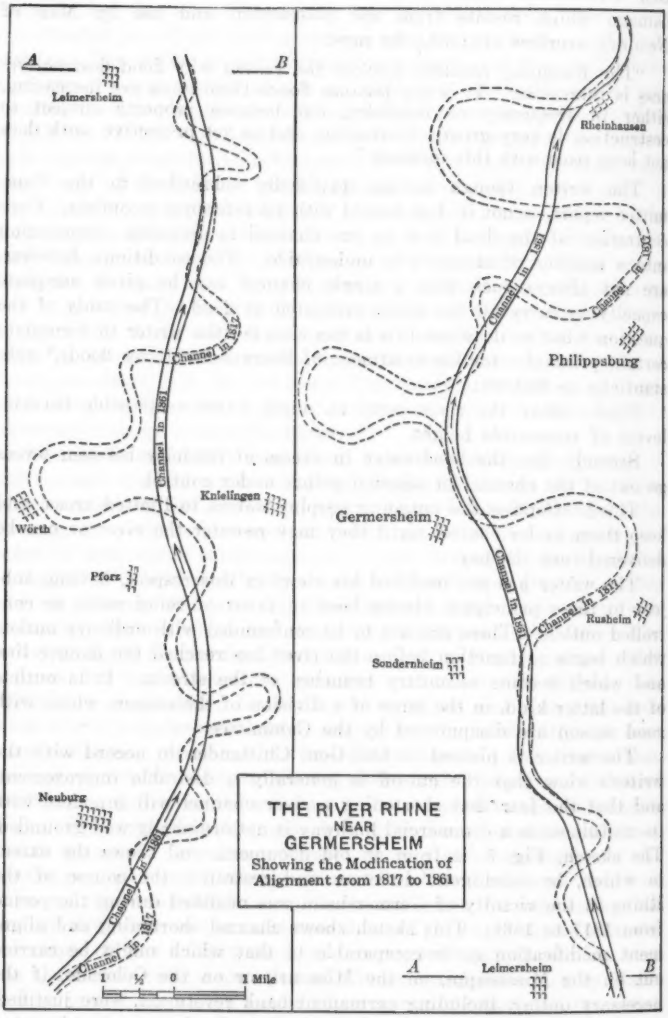

FIG. 5.

limit to the alignment corrections which might otherwise ultimately be hoped for. Mr. Grunsky.

In the case of the Rhine, the 1817 channel length of 63.5 miles, covered by the diagram, was reduced by cut-offs and corrections of alignment to 27.6 miles. The river was shortened in this stretch by 46% of its original length. Though a stream of considerable magnitude, having a width of about 800 ft., the channel control was effected successfully by excavating guide channels, by constructing training walls of fascines and brushwork, by obstructing the old channel with dams and dikes and, finally, by bank revetment and protection wherever the river in its meanderings reached the prescribed alignment. The channel improvement of the Rhine was not confined to the stretch shown by Fig. 5, but extended for miles in both directions therefrom—up stream as far as the Swiss boundary and down stream to below Mannheim at the mouth of the Neckar.

C. McD. Townsend,* M. Am. Soc. C. E. (by letter).—In submitting a closure to the discussion of the Report of the Special Committee on Floods and Flood Prevention, the writer has been impressed with the force of Bishop Warburton's remark that "Orthodoxy is my doxy". There is a tendency by various members of the Society to criticize the Committee for not giving special emphasis to the particular "ism" they advocate, without giving due consideration to the difficulties of formulating any report on which the Committee could agree. Mr. Townsend.

The subjects which were before the Committee have been discussed for many years, and most of its members had positive convictions which, if each had insisted on expressing, would have led to as many reports as there were members. A series of such essays would not have had much weight with legislators or the general public. Mr. Leighton lays particular stress on the necessity of engineers—and particularly of this great National Society of Civil Engineers—influencing legislation. The only way such results can be obtained is by united action. It became necessary, therefore, for the Committee to seek some common ground on which its members could agree. It was the realization of the necessity of adjusting divergent views, if results of value were to be obtained, not the shirking of duty, which led the Committee to make the safe and conservative report which Mr. Leighton criticizes.

Others criticize the report because it does not discuss the subject in sufficient detail. This phase of the subject was considered by the Committee, and it was found that the territory is so vast, the problems arising in various sections of the country so different, that either general principles, alone, could be enunciated, or a treatise of interminable length, based on incomplete data, would have resulted. A

* St. Louis, Mo.

Mr. Townsend.

brief report, therefore, was agreed upon, leaving to the members the privilege of elaborating, in the discussion, such details as they considered advisable.

The science of river hydraulics is not in such a nebulous condition as Mr. Eakin appears to think, nor does the river engineer have to be guided solely by the classic work of Humphreys and Abbot. Although, possibly, American engineers have not investigated sufficiently the laws governing the flow of rivers, those of Europe have given the subject profound study. The researches of Fargue on the Loire, Girardon on the Rhône, Liliavski on the Dnieper, Hagen, Schlichting, and Jasmund on the rivers of Germany, and others, have revolutionized the science in recent years. Moreover, the Committee was not appointed to write a treatise on river hydraulics, and could assume that the rudimentary laws governing the flow of water in rivers were known to members of the American Society of Civil Engineers. It is evident from the discussion, however, that many do not realize sufficiently the differences between the laws governing the flow of water in pipes, sewers, and other channels having an immovable bed, and those which govern the flow in a stream having a bed which fills or scours with changes in velocity. Van Ornum's "Treatise on the Regulation of Rivers" and the second edition of Thomas and Watt's "Improvement of Rivers" throw considerable light on the subject, and are more suitable sources from which to seek information than a report on Flood Prevention.

In the minority report, a similar assumption is made. Although the majority of the Committee states that the physical data are lacking on many streams to enable them to solve the problem of flood control properly, they are not prepared to admit that "extensive studies are needed regarding the physical and physiographic laws affecting stream loads, rate of transportation and deposition and the variation of these factors with different conditions" before they can solve the problem if the physical data are supplied.

It is so self-evident that, at such times as the ground is frozen and trees are without foliage, these conditions prevent the utilization of reforestation or ground storage, that there is no necessity of making such a statement in a report. The point the majority of the Committee makes is that, if floods occur under such conditions, there is no need of discussing the effects of reforestation or ground storage. It would be just as pertinent to investigate the porosity of the soil under an asphalt pavement when designing a sewer to carry the water which flows over its surface.

It is the writer's opinion that all investigations of the absorptive powers of different varieties of vegetation and the percolation through different kinds of soils are more valuable for studying problems of irrigation and drainage than those of flood control. Though it is con-

Mr. Townsend.

sidered perfectly feasible to measure these elements within a limited area and for a single river, the writer agrees with Gen. Chittenden that a determination for one situation, or season, or stream, would never apply reliably to any other. Moreover, to determine absorption of soils, it is necessary first to measure the run-off. When the discharge of a stream is determined, it is of no particular value to the problem of flood control whether the remainder of the rainfall has disappeared by evaporation or soil absorption.

The writer has recently investigated floods in Kansas, and they afford a pertinent illustration of this principle. During the summer the soil of Kansas provides a reservoir of enormous capacity, having a power of absorption which has been approximately measured by the Geological Survey. When the soil is prepared to receive it, a heavy rainfall will be accompanied by an exceptionally small run-off, but such conditions are of no value in determining flood prevention, as violent floods do not then occur. The floods in Kansas arise either from storms in February or March, when the ground is frozen and cannot absorb moisture, or in summer from a second storm which sweeps over the country within a few days after the reservoir capacity has been exhausted by a preceding rain. The run-off during ordinary conditions does not enter into the problem.

The majority report emphasizes the fact that reservoirs cannot be utilized simultaneously to reduce floods, to regulate the low-water discharge, and to increase the water-power that can be developed. The minority report seeks to minimize the effect of this statement.

There have been constructed at the head-waters of the Mississippi River a series of reservoirs primarily to increase its low-water flow. The practical manipulation of these reservoirs forcibly illustrates the necessity of the remarks in the majority report. Those who have meadows below the reservoirs demand that the flow be regulated so as not to interfere with their hay crop, those who raft logs want sufficient current to assist their business, and those who control water-power want a constant flow; in times of floods, those living above the dams are insistent that the gates be opened so as to reduce gauge heights on the upper river, and those below demand that the gates be closed to protect their property from overflow.

The statement that levees increase the reservoir capacity of the river channel appears to require further explanation. The construction of levees has increased flood heights on the Mississippi River between Cairo and New Orleans from 6 to 10 ft., and, as the levees are several miles apart, there is an enormous increase in the channel capacity during floods in this distance of 1 000 miles. As an illustration, the channel capacity above the overflow stage is given and compared with that of the Roosevelt Dam, but, as Gen. Chittenden states, the channel capacity of a river is by no means comparable in effect

Mr. Townsend.

with that of a reservoir. The slope of the river is an important factor in the problem. The greater the slope the less being the influence of the channel capacity on flood heights; but, under favorable conditions, its influence is very large. Notwithstanding the inflow of tributaries, the maximum discharge of the Mississippi River at Vicksburg rarely equals that at Cairo, nor at New Orleans that below Red River Landing.

The straightening of a river has been a subject of discussion by European engineers for many years. Prior to 1890, German engineers generally adopted the idea that, in improving rivers for navigation, the channel should be given a uniform width, bends should be eliminated, or at least be given as gentle a curvature as practicable, and the river forced to a uniform slope, the natural gentle slope in pools in some cases being destroyed by submerged dikes extending out from the concave banks. The improvement of the Rhine, cited by Mr. Grunsky, and that of the Danube, cited by Gen. Chittenden, are examples of this type of improvement. It was also adopted by the Missouri River Commission for that portion of the Missouri River between Jefferson City and the Gasconade.

Difficulties, however, were experienced with this method of improvement. No matter how much care was exercised, the slopes through the improved reach could not be maintained as designed. At the upper portion, the water surface was gradually lowered, and a bar as invariably formed below it; an improvement in navigation was created through the reach, but the channel, both above and below, had less depth than existed formerly.

In a paper presented to the International Navigation Congress of 1894, on the "Improvement of the Rhône", M. Girardon called attention to these difficulties, citing as an example the portion of the Rhône called the Canal de Miribel.

He states:*

"The works were carried out according to this programme and finished in 1857; the resulting improvement was very evident and the navigation, in place of the continual uncertainty in which this passage left it, found in the canal of Miribel a channel easy to follow and of sufficient depth at any time of year. For several years this improvement appeared to be the only result of the works and nothing indicated that they could have any inconvenient consequences. Nevertheless the bottom of the canal was attacked; lower measurements began to be registered at low water than before the works were executed and these got lower and lower, while at the exit they marked higher and higher; then the foundation of the works, which had been made at low water-level, appeared in the upper portion of the canal and was even uncovered at the mean summer level of the water, while below the same water-level the tow-path was submerged and became useless throughout

* Official Translation of the Congress, pp. 27 to 29.

Mr. Townsend.

the greater part of the year. It became necessary to improve this situation which might at any time become very serious. The towpath was first raised over half the length, that is the part submerged; then to arrest the movement it was decided to lower the dividing dike and to cut down the dam of Thil as low as possible, in order to allow the greatest possible volume of water to find its way through the false branches, not only in floods but also at the mean water-level. It was supposed that by this means the main branch would be relieved and that by decreasing the volume of water which crossed it its scouring action would cease. The result aimed at has been partly realized; the movement of the profile has become much slower, but has not entirely ceased; and although the volume of water which passes into the canal has become notably less, the incline [slope] which will set up any equilibrium between the resistance of the bottom and the effective force of the current under the new conditions of depth has not yet been attained.

* * * * * * *

"Thus in spite of the improvement realized, in spite of the enormously extensive alterations that the river has undergone while passing between the constant banks, neither regularity in the cross-section has been obtained, nor constancy in the mean depth, nor uniformity in the incline [slope]; and the bed that has been opened remains formed as everywhere else of a series of hollows [pools] separated by ridges [bars], while the profile presents a series of reaches with a comparatively feeble incline [slope] separated by falls.

"Outside the canal the general incline [slope] of the combined streams at the entrance to Lyons, at kilometre 5, where the profiles join, has not sensibly varied; it was and still is 0.81 m. per kilometre, but its distribution has changed considerably. Throughout the canal, from kilometre 8 to kilometre 25, it was 0.883 m.; it is not more than 0.696 m. per kilometre on the other hand above the canal; from kilometre 25 to kilometre 34 it has been raised from 0.75 m. to 0.96 m., and below kilometre 8 to kilometre 5 it has been raised from 0.49 m. to 1.06 m. per kilometre."

The profile, Fig. 6, derived from De Mas' "Rivières à Courant Libre", illustrates the condition.

Similar effects have been observed on western rivers of the United States. In the improvement of the Middle Mississippi below St. Louis the river was straightened for more than 20 miles. As a result, the slope was reduced at low water from above 0.6 to 0.25 ft. per mile, and the low-water surface of the river at the Eads Bridge was lowered about 3 ft. An excellent channel exists through the improved reach, but the slope on the Chain of Rocks, above the city, has been increased, and dredging is required annually immediately below this reach in order to maintain the required channel depth. Similarly, the Kaskaskia cut-off, above Chester, which shortened the river about 6 miles, has a low-water slope through it of 0.23 ft. per mile, but dredging is required annually on the crossings above and below.

Mr. Townsend.

The improvement of the Missouri River reduced perceptibly the low-water plane at Jefferson City, and a cut-off at Camden Bend, which occurred in 1915, has created a bar 2 miles below it over which on November 3d, 1916, during an inspection trip made by the writer, a boat drawing 3½ ft. had to be sparred, the gauge at Kansas City reading 7.8 ft. At the bend above Omaha Mission, about 764 miles above the mouth, during the June flood of 1916, another cut-off occurred, and on October 20th the snagboat *McPherson,* drawing 3 ft., had to be sparred over shoals, both above and below this cut-off, the Omaha gauge reading 6.4 ft.

On the Arkansas River, a very forcible illustration of the effect of cut-offs was also afforded during the flood of 1916. In prehistoric times the Arkansas River, by the caving of its banks, broke into the

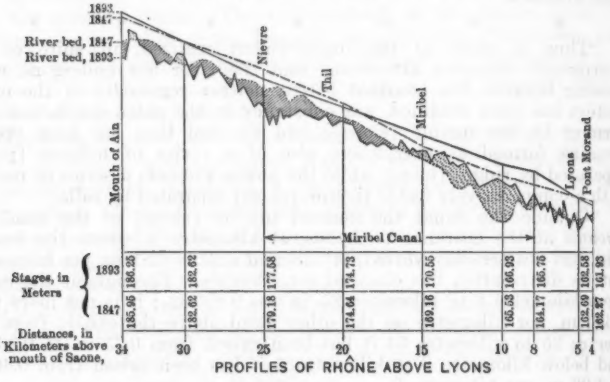

FIG. 6.

White River, about 10 miles above its mouth, and, until this season, the low-water discharge of the Arkansas emptied into the Mississippi through the mouths of the White. The cut-off between the two rivers gradually increased in length, and a sharp bend developed. During the flood of 1916 a cut-off occurred across this neck, resulting in such a shoaling in other portions of the old channel that at the present time (November, 1916) the Arkansas River has resumed its old outlet into the Mississippi and now discharges its low-water flow in a separate channel from the White River.

On the Red River numerous cut-offs have occurred, with results equally disastrous. Near Duke's Plantation, below Garland, the cut-off of 1915 created a bar below it over which at the next low water the depths of the navigable channel did not exceed 1 ft., and the efforts of the river to increase its length by caving after these cut-offs occurred

have been destructive of the levee line which had been constructed along the river banks. Mr. Townsend.

It is the raising of the river bed, not the increase of the discharge, which raises the water surface below cut-offs. The French engineers have called attention to this, and their views are now generally accepted in both Germany and Austria.

In his work on the improvement of the Rhine, Mr. Jasmund discusses the straightening of that river (cited by Mr. Grunsky) and explains that it is due to a previous undue reduction of slope, in former attempts to improve the river, that renders these cases exceptional, and conveys the impression that he disapproves of cut-offs on other portions of the Rhine.

The straightening of the Danube River in the vicinity of Vienna, quoted by Gen. Chittenden, did not improve the navigation of the river as much as was anticipated. About 3 500 000 cu. m. of material were scoured out of the cut, and deposited in the river below, raising its bed, and extensive work has since been required to adjust the low-water channel to these new conditions. It has even been necessary, in order to stabilize the bars, to create in the low-water channel new sinuosities to replace those cut out in the original improvement.

The view that a sedimentary stream seeks to regain its length after a cut-off did not originate on the Mississippi River, but is a corollary to views advanced by Guglielmini more than 200 years ago from observations he then made on the Po. Observations made recently by the Mississippi River Commission confirm this theory. Guglielmini's general principle, that there is a relation between discharge, slope, and the character of the soil, has also been verified by the changes which have taken place recently in the Atchafalaya and Illinois Rivers. In both these rivers a change in their discharge created by artificial means has been accompanied by a marked change in the radius of curvature of bends. A citation of an unreliable reconnaissance by Lewis and Clark is not considered sufficient proof to overcome the overwhelming evidence that can be cited to prove that rivers do strive to adjust their length to their discharge and slope.

Gen. Chittenden also takes exception to the distinction made by the Committee between streams created by glacial action and those carrying a large quantity of sediment. Although not agreeing with Mr. Fuller, that there is a necessity for a new variety of engineer, called by him the geological engineer, the writer believes that all engineers who investigate river problems should have knowledge of geology. The methods of improvement which are successful with the gentle slope of rivers created by glacial action have frequently failed when applied to streams carrying large quantities of sediment. Thus, on the rivers connecting the Great Lakes a permanent channel of 21 ft. can be dredged, but on the Mississippi a channel dredged to 9 ft. fills annually. The permeable dikes, so successful on the Middle

Mr. Townsend.

Mississippi, were failures when applied to the Upper Mississippi above Keokuk. On the Illinois River a cut-off could be made with impunity, but the writer believes it is impossible to improve the Missouri River permanently unless cut-offs are prevented.

In reference to outlets or spillways, the writer does not apprehend the danger to the channel of the main river from their construction that some do. He is a firm believer in the idea that rivers have a tendency to correct man's errors, and that, if outlets are constructed, a fill will occur in the outlets rather than in the river channel; but, if the outlet is given such dimensions that it begins to enlarge, there is imminent danger that the main channel will not only fill but be abandoned, unless the process is checked. A river exhibits an objection to serving two masters.

Mr. Knowles.

MORRIS KNOWLES,* M. AM. SOC. C. E. (by letter).—In contributing to the closure for the Minority, the writer expresses the conviction that the character of the discussion presented demonstrates conclusively that the attempted premature discharge of the Committee, on two occasions, and before a final report was submitted, was an unfortunate mistake. It is evident, also, that the discussion has fully justified the contention of the Minority that assertive statements, with a limited point of view only, and in the face of present divided opinion on the subject, will not promote progress or the development of a much needed comprehensive programme for stream control, but will rather intensify discord where it is not necessary. The object of the Committee, in so far as it could not agree on a final pronouncement, ought to be to promote further investigation and discussion, and not to attempt to close the door by dogmatic expression of a single point of view.

It is apparent, at a time when the importance of regulation of stream flow in its largest sense, which includes flood control as a part, is engaging the attention of the country and impressing itself on laymen, that the Society has lost a wonderful opportunity to promote sound thinking and the development of a programme looking toward wise legislation. It is plain from the public interest, general discussion, and proposed laws, that no one type of control is a universal panacea, or will do for all classes of streams; also, that the opinion of a single branch of scientific men, not in sympathy with all phases of stream regulation, will long satisfy the country, for such opinion will stifle progress and unduly lengthen the period required for reaching the desired results.

The writer expresses the hope, therefore, that, at some later date, the Society may take up this important subject again and continue its consideration until it becomes possible to prepare a report which will merit the consideration justified by the high standing of the Society.

Paper No. 1401

FINAL REPORT OF THE SPECIAL COMMITTEE TO FORMULATE PRINCIPLES AND METHODS FOR THE VALUATION OF RAILROAD PROPERTY AND OTHER PUBLIC UTILITIES*

WITH DISCUSSION BY MESSRS. J. E. WILLOUGHBY, C. E. GRUNSKY, JOSEPH MAYER, AND W. R. MCCANN.

COMMITTEE:

FREDERIC P. STEARNS, *Chairman*,

CHARLES S. CHURCHILL, HENRY E. RIGGS,

WILLIAM G. RAYMOND, JONATHAN P. SNOW,

WILLIAM J. WILGUS,

LEONARD METCALF, *Secretary*.

* Presented to the Annual Meeting, January 17th, 1917.

PREFACE.

In presenting this report to the Members of the American Society of Civil Engineers, the Committee is fully alive to the fact that the art of valuation is still in formative condition, as is evidenced by the conflicting views expressed, or principles enunciated, even by the higher Courts. That debatable subjects arise frequently, and will continue to do so, is indicated by the record of the Committee's work incident to the rendering of this report, for in spite of the prior knowledge of its members on this subject, and professional experience in it, five years have elapsed since their appointment, in which forty-eight joint meetings have been held, many of them consisting of three sessions, and a voluminous correspondence has been carried on, aggregating thirteen substantial volumes.

Nevertheless, the fact that nine men of widely different training and experience, practising in different professional lines and fields, have been able to come finally to common belief upon most of the subjects discussed—the principles which should control the valuation of normal public utility properties—leads the Committee to hope that this report may be helpful to others, and may serve to clarify this very involved subject, to the common advantage of public service corporations and the public served, by aiding in the establishing of procedure and in the reducing of the uncertainties of valuation and rating of public utility properties.

Where differences of opinion have developed, the conflicting views of the Court have been cited, the effect of the application of different theories indicated, and the course of action most likely to lead to a fair settlement of debatable questions has been outlined.

The Committee bespeaks a thorough and open-minded study of the whole report, by the members of the Society interested in the subject. Only with such a background will its full significance be apparent. The subject is so involved and many-sided that brevity and conciseness are not always possible, and that brief statements may not always be capable of isolation from the context without the possibility of causing ambiguity; therefore, though the Committee has prepared an abstract of its conclusions for the convenience of the readers of the report, it hopes that the members of the Society will base their conclusions and discussions on the main report, rather than on the abstract.

The table of contents follows. Thereafter are given, successively, the abstract, the introduction and other chapters of the report, and finally a detailed glossary.

October 28th, 1916.

ABSTRACT OF REPORT.

The Committee, in its consideration of the subject assigned to it, has been guided by the belief that stress should be laid on fundamental principles and on general methods rather than on details which necessarily vary under different circumstances; that the discussions, unless otherwise stated, should be confined to normal properties; that valuation should have its foundation in fact; that where there are alternative methods equally fair to the parties affected, the one should be selected which is most capable of being carried out effectively under present laws, as defined by the Courts, and which is most desirable for general use in the direction of uniformity; that recognition should be given to the interdependence of the various elements which enter into the problem; that while major attention should be given to the ascertainment of the cost of creating the property in question and its business, due consideration should be given to intangible values, and that the important item of interest, in this report meaning interest compounded annually, should always be considered.

In the light of this preliminary understanding and of the discussions which ensued, the following conclusions have been reached.

Fundamental Principles of Valuation.

The principles and methods must be such that when properly applied the result will be fair to all parties affected and of a nature that will attract to the service of the public capital necessary for building new properties and for improving and extending old ones.

New Properties.—In the valuation of a new property, if the question of a fair return is at stake, the actual investment in the portion devoted to public use, including working capital and development expense, should be taken as the basis for "fair value"; if the same property just ready for operation is to be valued for public acquisition, the basis of "fair value" should be the actual cost, including the money value of services and other considerations involved; if the valuation is to be used for capitalization, the result should be attained in the same way as the return base, except that all parts of the property should be included; and if for taxation, whether of a new or old property, the result must accord with the laws of the State, or, where not governed by such laws, should, to make it equitable, be fixed at a sum consistent with the valuation of other property for taxation.

Old Properties Under Continuous Regulation.—In the valuation of an old property, operating without competition and from its inception under commission control as to rates and methods of accounting, and assumed to have been entitled to earn sums sufficiently large to provide for all expenses of maintenance, operation and taxation, depreciation allowances, and a fair return on the "fair value" of the prop-

erty, the owner should be compensated in some way for losses that he may have sustained during the early years of operation before the property was tuned up and the business developed, either by including in the valuation the sum of the deficiency of earnings in the early years, with interest, or by allowing higher rates of return in subsequent years to offset the early deficiency.

Old Properties Not Under Continuous Regulation.—In the valuation of an old property which has not been subject to continuous regulation, not only are the foregoing principles important, but there are many cases in which equity calls for the inclusion of not only the sum representing the sacrifice by the owner but also a further positive or negative sum representing valuable property or rights which may have been acquired or lost by the owner as a result of time or through the failure of the public or the owner to assert their authority, the Courts holding that the present value of the property should be used rather than its cost.

Physical Property to be Included in Valuation.

This varies in different cases with the use to which the valuation is to be put and the law governing the case.

Used and Unused Property.—In cases of rate regulation, only the property considered to be devoted to public use should be included, embracing that which is in active use and also that which is properly and reasonably held in reserve to insure the safety, economy, sufficiency, and continuity of service. In valuations for capitalization and public acquisition it is obvious that all of the property in question should be included.

Retired or Discarded Property.—Plant units which have been definitely abandoned and are not likely again to be used, due to having been worn out in service or by reason of the reconstruction of the property, should be excluded from the valuation and should appear either in a separate schedule of retired or discarded property, or such full statement of the conditions should be made as will definitely fix the status of the units or parts. Temporary works necessarily built in connection with, or required for, the construction of permanent works, or for furnishing service to the public at an earlier date than it could be furnished by the permanent works, should be included in the valuation.

Excessive Size or Capacity.—No reduction should be made in the valuation on account of excessive size or capacity, except when the excess is so great as to be clearly unreasonable and is the result of not using proper foresight.

Donated Property.—Lands or other property voluntarily donated to a public utility should be included when determining the reproduction cost, on the same basis as land and property otherwise acquired.

Leased Property.—In the case of leased property, either the property itself or the lease should be valued, as circumstances may dictate.

Title to Property Not Conclusive.—Structures located on land to which the owner of a public utility has no title should be *included* in the valuation of the property where the owner has been required by law or necessity to pay their cost, including in this class also property voluntarily donated; and they should be *excluded* where other public service companies, the public, or the users, other than the owner in question, have been required by law or necessity to pay their cost.

Working Capital.—It is customary to include under the term "working capital" the amount of cash, materials, and supplies, provided for use in the plant, but not yet forming a part of it, and other current assets which are essential for the proper maintenance, operation, and administration of a property. There should be included in a valuation an amount of working capital sufficiently large, not only to meet the usual requirements, but to provide for emergencies.

Securities Owned.—Ordinarily, the valuation of property devoted to public use should not include securities owned, or surplus cash not forming a part of working capital, except in instances where such securities and surplus cash are an offset, in whole or in part, for depreciation deducted from the cost of the property.

Original Cost to Date.

As defined by the Committee, this is the first cost of the identical property units now in use, including overhead charges.

Difficulties.—While much of the difficulty of determining original cost as thus defined in some cases may be removed, especially in the case of short-lived property, it is not feasible to obtain a dependable result where the absence of reliable historic data makes necessary a resort to estimates, as in the case of old properties consisting mainly of long-lived items.

Schedule.—Generally, it will be found necessary to prepare a schedule in the same way that one would be made for determining the cost of reproduction, many adjustments in the records often being required, even under the most favorable conditions, in order to obtain correct results.

Costs—Unit Costs.—When a schedule is necessary, the corresponding costs or unit costs are essential to the completion of the inventory, and where these are unobtainable, as is usually true in the case of property units acquired or created long ago, the ascertainment of the original cost is impossible.

Overhead Charges.—These are recited at length in the section relating to cost of reproduction. They are inadequately reflected in the records, as a rule, and therefore adjustments are required which are largely matters of opinion and speculation, and which, in conse-

quence, make more uncertain the final result thus often destroying its usefulness.

Development Expense.—The expense, actually incurred in connection with the tuning up and creation of the business of a property, should be included as a part of the original cost to date.

Cost of Reproduction.

Theory of Reproduction.—Estimates of the cost of reproduction should be based on the assumption that the identical property is to be reproduced, rather than a substitute property; that while apparent present-day conditions, that would affect the cost of reproducing the property, must be considered in any logical estimate, yet history must also be considered, to determine what is to be reproduced, the conditions under which it is to be reproduced, and how the estimates must be made; that for all those items concerning which there can be no doubt the engineer should use the basis plainly applying, and that for those that are doubtful, or have been questioned, he should present the effect of the use of the different bases clearly, that the determining body may have the data for a wise decision; and that normal present conditions shall determine the prices and methods for doing the work.

Preliminary Work.—The first step in estimating the reproduction cost of a property is such a study of the property and its history as will enable the estimator to make a complete list of all items, lay out a proper financial and construction programme, and fix proper unit prices to the several items of the schedule, after which the property should be divided into groups of items or units which will lend themselves to the depreciation study and accounting, preferably following some well established classification of accounts.

The field schedules and inventories, suitably recorded on appropriate forms, should be based not only on full and complete surveys and inspections of the visible physical property, but they should also reflect a careful historical search of existing records of original conditions, and other reliable sources of information, bearing on items of material or work which entered into or were incidental to actual existing units, special care being exercised to exclude that which is not capable of definite proof, and to limit the speculative uncertainties as far as possible.

Unit Prices.—In determining unit prices a rational sequence of construction should be assumed for the reproduction of a property; and rational assumptions should be made as to the manner of doing the different parts of the work, whether by the forces of the company or by contract. Unit prices based, where possible, on the actual cost of doing similar work, in a similar manner, under similar circumstances, should be determined by persons of experience and sound judgment. They should be based on the normal average cost of work

for a considerable period—say, 5 or 10 years—in order to give stability to the valuation, so that it may be used for a subsequent term of years. In the case of items which are steadily increasing or decreasing in value, the prices adopted should be normal for the time of the valuation. Full consideration should be given to the time allowed for construction, to climatic conditions, and to the effect of any other significant conditions or limitations upon the cost of the work.

Land Holdings.—Separate parcels of land, such as one or two lots, or a tract of not unusual size, not connected with other lands of the utility in a strip or body, and where freedom of choice in selection may be exercised, should be valued on the same basis as other lands in the vicinity, used for general purposes.

Where large tracts have been acquired, made up of a number of separate entire parcels, the history of the transaction should be completely investigated and allowance made in the estimate for costs of vacation of streets, or acquisition of other rights, incident to the use of the property as a whole. Such further allowances should be made, as may seem to be justified by experience, to cover excess costs, over and beyond the normal market values which existed at the beginning of the project, and which were due to fluctuations of price or other causes beyond control. Normal market values of similar and near-by property, as of the time of appraisal, should be the basis, with such additions as are warranted by the investigation in each case.

In the consideration of values of lands, for rights of way for a railroad, an electric railroad, an aqueduct, or other like property, or, lands for a water-works or an hydro-electric reservoir, where freedom of choice is restricted and where all the land must be acquired, radically different methods must prevail.

In the valuation of lands of this class, a clear distinction should be made between:

(*a*) Lands where the entire tract or parcel is taken and there is no element of severance damages;

(*b*) Lands where only a portion of the tract is taken and where the element of severance damages is present;

and the extent of lands of both classes should be shown.

Historic conditions, where ascertainable, should be given due weight in fixing the extent and character of the severance. All elements of value to the seller, including recognition of all damages to the portions of his property not taken, which would prevail in the case of condemnation of the lands under reproduction, should be considered.

A determination of the relation existing between actual recent acquisition costs and the normal market value of the lands out of which the strip or parcel was taken at the time of acquisition is undoubtedly possible in many cases. It would seem that where such relation can

be determined, its use in connection with the normal market values of these or similar lands at the time of appraisal should establish a reasonable cost of reproduction.

The determination of the figure to be used should be based in all cases on full consideration of the present normal market value of the area of land acquired and of other recent purchases by the same or other companies of similar lands in the vicinity or in districts of like characteristics; the damage to the remaining land, not required, due to severance and all consequential injuries; the amount and character of the costs of acquisition and overhead charges; enhanced prices due to active demand; and any other real items of cost which would be included in case of purchase. But no allowance should be included for special values coming after the acquisition of the property on account of its new use or on account of a greater earning power under the new use, or for any other hypothetical "value".

Estimates should be based on prices and values as of the time of appraisal, be they higher or lower than those prevailing at the time of original acquisition. The thing sought in reproduction is the fair cost of acquiring the property as of the date of valuation.

The treatment of the valuation of land holdings is not yet thoroughly crystallized; therefore the valuing engineer will do well to confer with counsel upon the interpretation of past Court decisions and the legal principles which are most fairly applicable to the case under review.

Overhead Charges.—There are certain expenses called overhead charges, inseparable from the construction of any property, which are a necessary and proper part of its cost, but which are not capable of physical identification after the completion of construction work. These expenses cannot be covered in the estimate of "Cost of Reproduction" by the application of specific unit prices; from their nature they attach to the whole or large parts of the property rather than to any particular units.

Among the expenditures which must be provided for, and classed as overhead charges are:

(*a*) Cost of promotion;
(*b*) Cost of financing and securing the necessary capital with which to carry out the enterprise;
(*c*) Cost of organization, including the incorporation and organization of the company, securing of franchises, and other like expenditures;
(*d*) Engineering, including the making of the preliminary investigations and plans, plans for the construction of the entire property, the engineering supervision of all construction and other work involved in the development of a property, except

such direct supervision as may properly be included in the unit prices of various property units, or as specific charge against some particular schedule or group of units;

(*e*) Administration, including salaries for general officers, agents, accountants, clerks, and other assistants, not included in the engineering and legal departments, and all administration expenses;

(*f*) Legal, including salaries and expenses of law officials and costs of litigation which, depending on the character of the property and its location, may be a comparatively minor item or a very large one;

(*g*) Interest during the period of construction, on money borrowed, or on money invested in the property by its owners;

(*h*) Taxes and insurance during construction; and

(*i*) Contingencies, representing expenditures which cannot be foreseen but which from one cause or another are always of considerable size in the construction or reproduction cost estimate of any great enterprise.

Depreciation and Appreciation.

With a desire to remove the ambiguity and resulting confusion that has attended the use of the term "depreciation" in connection with valuation, the Committee has considered the subject from three standpoints: (1) the cause, *decretion* or loss of service life; (2) the record, *accounting depreciation,* or the money allowance made in bookkeeping to offset accruing loss of service life; and (3) the amount sought, *depreciation of valuation* or *fair depreciation,* the sum which should be deducted from original cost to date or from estimated cost of reproduction new as a step in finding that which the Courts have called "fair value".

Decretion.—This is the fact of loss of service life of a physical property, or property unit, or item, regardless of its effect on value or anything else. It may be due to use, or inadequacy, or obsolescence or accident, either singly or in combination in a given plant or plant unit.

Although, in a well-maintained property, decretion is always present in some degree, yet in some cases this decretion, converted into loss of value, which loss is hereafter called cost of decretion, should not be considered to be a deductible quantity in finding the value of the property—that is, it should not be considered as *depreciation of valuation,* or *fair depreciation.* Unfortunately, this has not been entirely understood.

Whether or not, and to what extent, if any, the loss of value due to existing decretion shall be deducted from original cost to date or cost

of reproduction new, when finding "fair value" for any purpose, is the great troublesome problem of depreciation in valuation.

Accounting Depreciation.—The fundamentals of the methods of accounting for depreciation are that the owner of a public utility is under obligation to the investors in its securities to maintain the integrity of the investment as a continuing property and to furnish suitable service to the public; that the public is under obligation to the owner to pay a fair price for the service rendered, which should cover all operating expenses, a proper allowance for depreciation and a fair return upon the "fair value" of the property; and that the return to the investor and the rates to the consumer should be kept reasonably stable and uniform from year to year and should be fair.

The four accounting methods in use for accounting for depreciation, the *replacement method,* the *straight-line method,* the *compound-interest method* (formerly called by the Committee the "equal-annual-payment method"), and the *sinking-fund method,* yield identical total costs when the whole life of a property unit is considered, and any one of them seeming to be the most convenient may be chosen, provided only that under the circumstances it is legal, safe, and fair.

The replacement method is applicable to those short-lived properties or parts of properties made up of a large number of items, the replacement or retirement of which proceeds after a time with fair regularity and causes no troublesome variations in return or service rates; the straight-line method applies to any property units having more than a year of service life, which are assumed to depreciate uniformly from the beginning to the end of service life; the compound-interest and sinking-fund methods apply to property units the depreciation of which is assumed to progress at the same rate as a sinking fund grows from an annuity, accumulating at compound interest.

In addition to these four methods there is the unit cost method, eminently sound in theory but not readily applicable to accounting purposes, which is based on the conception that the value of a plant unit should be decreased from year to year to such an extent that the cost per unit of output or service, taking into account all annual charges for interest, depreciation, repairs, cost of operating, etc., should be constant during each year of the estimated service life of the unit.

The great discrepancy in the growth of depreciation of long-lived units under the straight-line and compound-interest theories should be carefully noted when determining which method to use.

This report is particularly concerned with depreciation accounting as it relates to valuation, and the determination of the depreciation of valuation. It would seem to be fair in any given case to give the method of accounting used by the utility in setting up depreciation

allowances its proper effect in determining deductible depreciation or the depreciation of valuation.

Depreciation of Valuation Dependent on Accounting Methods and Regulations.—Finding the cost of decretion, here defined as the loss of service life of an item converted into loss of value, is a step in the determination of depreciation, but whether and to what extent, if at all, the estimate thus found shall be treated as depreciation of valuation may be, and very probably will be, dependent, at least in part, on the methods of accounting for depreciation and the character of regulation that have prevailed.

Depreciation of Valuation under Replacement Method.—If by order or sanction of a regulating body, or by long-continued proper custom under no regulation, a property, as for instance a railroad, has been maintained in normal working condition, necessarily less than new in some or all of its parts, by the replacement method, and at any given date is being valued for any public purpose and at that date shows normal condition, all its several parts being in as good condition as could be expected, the accounts showing that those amounts have been expended in renewals that were necessary to keep the property in normal working condition, and the fact appearing that no expenditure reasonably to be expected could put the property in better than the normal condition in which it is found, and that no unusually large expenditure is presently to be necessary for this purpose, then, in spite of the fact that there is an existing decretion in its several parts, there should be found no depreciation of valuation. Under the method of accounting, the public has not paid, and could not pay, for the accrued depreciation, and under this condition its accrued obligation to pay should be considered an asset of the company owner.

If parts of the property are maintained under the replacement method and part by some proper allowance method, then, except as noted below, depreciation of valuation should be found with respect to those parts maintained under the allowance method, but this depreciation of specific physical units will be made good in whole or in part by existing funds or property purchased with allowances, either or both of which will be included in the valuation as they are found.

If in the judgment of the valuing engineer, the replacement method may not be used with propriety for a given property, either because not in accordance with law, or because the method is not adapted to the property, then, whether or not the property has been maintained in the past under this method, the valuing engineer should estimate depreciation of valuation in the amount of the cost of the decretion he finds. There can be no certainty that the property will be properly maintained in the future.

When a comparatively new property, other than a railroad, is to be valued, and it has not been under any regulation that has affected

its accounting methods, the law as laid down in the Knoxville decision would seem to make it necessary to find depreciation of valuation in amount equal to the cost of decretion found for all items, whether or not maintained by the replacement method. The Committee, however, believes that this may work hardship and injustice in some instances, and suggests that in such cases the facts be reported with such recommendations as to equity, as may seem fair to the engineer.

Depreciation of Valuation under Allowance Methods.—If either the straight-line, compound-interest, or sinking-fund method has been used in computing depreciation, and the method of accounting for it has been prescribed by a regulating body or voluntarily followed by a company owner from the beginning, the same theory, so far as it applies to the property in question, should be used for estimating the cost of decretion; and the entire cost so found, lessened by any accumulated depreciation funds, will appear as depreciation of valuation, unless the sinking-fund method of accounting has been used. In the latter case, if the valuation has to do with the reasonableness of the return and the accounting is to go on as before, apparently existing depreciation would not be *depreciation of valuation*, and therefore would not be deductible; but if the valuation has to do with condemnation or purchase, then, as in other cases, the apparently existing depreciation is depreciation of valuation, and the owner should receive the depreciated value of the physical property and the existing fund.

Effect of Regulation on Depreciation of Valuation.—Regulation which determines the method of accounting will in part determine the amount of depreciation of valuation when finding "fair value", because it determines the method by which the public shall pay for the loss of service life. If the regulating body has prescribed the replacement method for the whole period that units have been in existence, then, although depreciation may exist, it is not depreciation of valuation, because, under the method of accounting, the public has not paid, and could not pay, for the accruing depreciation, and is still under obligation to pay for it.

Methods of accounting in force at the present time which make proper provision for the accruing depreciation should not have full weight, if, in previous years during the life of the property units, other methods were in use which did not make provision for such depreciation. The amount of depreciation of valuation in such cases should be equivalent to the accumulated contributions of the public for depreciation allowances under the various methods of accounting which have affected the property unit from time to time. The public is still under obligation to make good that part of the loss of service life not yet paid for, and this obligation should be considered to be as much the property of the company usable to offset accrued depreciation as renewal funds or property actually in existence.

Whether or not this reasoning will stand in any case is for the Court to determine. Valuing engineers and accountants should report what they find as to the actual cost of decretion, and the sums which have been received to offset such cost, under the methods prescribed by the regulating body from time to time. They may give their opinions as to the amount of depreciation that should be deducted from cost to find cost less depreciation as an element in the quantity known as "fair value".

If regulation has not fixed accounting methods, but has limited the earnings, it should be permissible to inquire whether the limited earnings have been sufficient to pay operating expense, depreciation, and fair return. If so, depreciation found should be considered depreciation of valuation to the extent warranted by the accounting methods lawfully or properly followed; if not, a question arises. It is remembered that the duty of the company owner is first to maintain the property "before coming to the question of profit at all", and that it is the duty of the regulating body to see that rates are such as to permit the company owner to earn operating expense, depreciation, and fair return. If the regulating body has made sufficient earnings impossible, is it still the duty of the company owner to maintain the property before paying fair return to its security holders? If it is, depreciation of valuation should be found in the amount of the total cost of decretion or so far as warranted by the accounting methods followed. If not, depreciation found should not be considered depreciation of valuation except to the extent covered by earnings after deducting operating expense and fair return. This is a matter of equity to be determined by a Court. If under regulation the property is a losing venture, it is not included in the class of properties now being considered. In any event the depreciation existing should be found and reported, together with all pertinent facts, that the Court may determine the equities of the case.

Conclusion upon Depreciation.—The valuing engineer should bear in mind that when a company owner has invested a reasonable sum in a property for public service, it is entitled to, but not guaranteed, a fair return on its investment, so long as the money remains in the property, either as property, or funds, or accrued public obligation to pay. Therefore, so long as the company owner keeps a sum equivalent to the total investment at work for the public, either as property serving the public, or funds held in reserve for such property, no policy should be followed in estimating depreciation that will reduce the property to a value less than the investment, or, when using cost of reproduction less depreciation, as a basis of "fair value", to a value less than the cost of reproduction of that part of the property estimated to have been created with company funds, acquired by gift, or in any way not the result of public contributions to cover depreciation.

Appreciation.—Appreciation, largely the result of solidification, seasoning and adaptation, represents the improvement in quality and usefulness of certain parts of the physical properties of a railroad or other public utility property, and it results from the lapse of time, from work not specifically charged to capital account, from maintenance, from use, etc., and covers items, not represented either by the quantities or unit prices, that are determined in connection with a valuation.

There should be no general setting off of appreciation against depreciation, but appreciation should be determined independently from depreciation. Care must be taken that items of labor and expense included in the estimate may not be duplicated in development expense.

Development Expense.

In the production of a normal going property, development expense, almost invariably, is an unavoidable real cost, and is measured by the difference between the amount which the company is entitled to earn in the early years and the amount which it actually does earn. The portion of this expense incurred in tuning up the property and bringing it to its present state of operating efficiency may be included in the cost of construction, and the remainder may be treated as the cost of acquiring the business.

Intangible Value.

The intangible value that pertains to a property and should be given due weight in the ascertainment of "fair value" is the difference between the tangible value—that is to say, proper cost including development expense, less depreciation of valuation—and exchange value, in which is reflected existing and potential dependable income and beneficial results. It embraces going value, in which is merged good will, franchise value, efficiency, favorable business arrangements and design; and it also includes other elements, such as leases, easements, water rights, traffic and operating agreements, strategic location and advantages, and other privileges.

CHAPTER I.

INTRODUCTION.

The Special Committee of seven, appointed by the Board of Direction in September, 1911, to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities, presented to the Board, early in December, 1913, a Progress Report on the subject of Valuation for the Purpose of Rate-Making.

One member of the Committee was unable to take any part in its deliberations, and consequently did not wish his name attached to the report, which was signed by all the remaining members, consisting of Frederic P. Stearns, *Chairman,* Leonard Metcalf, *Secretary,* Thomas H. Johnson, Alfred Noble, William G. Raymond, and Jonathan P. Snow.

The report was presented at the Annual Meeting of the Society on January 21st, 1914, and, after a brief discussion, the following resolutions were adopted: First, a resolution offered by the Chairman, as follows:

"*Resolved,* That the Progress Report of this Committee, together with all discussion thereon up to September 1st, 1914, or to such later date as the Board of Direction may fix, be referred back to the Committee for further consideration; and that in the meantime the Board of Direction be requested to assign a date for the written and oral discussion on the subject."

Second, a resolution offered by a member:

"That inasmuch as each member of the Society has a copy of that report, that it be not published in the *Proceedings* until the final report of the Committee is issued."

A special meeting for the discussion of the Progress Report of the Committee was held on March 11th, 1914, when the report was discussed by ten members of the Society, and the meeting was adjourned until April 2d, 1914, when it was again discussed in the afternoon and evening by fourteen members of the Society. The total number of written discussions to the present time is sixty-three, covering 340 printed pages of the *Proceedings.*

The Committee suffered a great loss by the death of two of its members: Thomas H. Johnson on April 16th, 1914, and Alfred Noble on April 19th, 1914. To fill the vacancies thus created, and a further vacancy caused by the wish of Henry M. Byllesby not to remain on the Committee, the Board of Direction on May 6th, 1914, appointed to the Committee Charles S. Churchill, William J. Wilgus, and Henry E. Riggs.

Several of those discussing the Progress Report contended that the Committee, in making a report on Valuation for the Purpose of Rate-Making, should have omitted railroads from its discussion, principally on the ground that railroads are competitive, and that their rates are to a large extent interdependent and must be fixed in accordance with these conditions. Some have gone so far as to infer that it was the aim of the Committee to suggest methods for determining individual rates to be included in a tariff, although there was no suggestion of this kind in the Progress Report, which dealt only with returns as a whole; that is, with the aggregate sum to be earned by means of the rates.

The Committee recognizes fully that an engineering valuation of the property of a public utility is only an element in fixing rates, and that this is especially so in the case of railroads and other competitive public utilities. It agrees with the view as to railway rates, expressed by Judge Prouty in his address to the United States Chamber of Commerce on February 11th, 1914, when he says:

"The rates of public utilities are at the present day usually fixed by commissions, both state and federal. It is perhaps the natural inference that when the value of the property has been determined and the rate of return fixed the work of the commission in establishing the charge of the public utility is comparatively easy. It is only necessary to multiply the value by the rate and to allow a charge which will yield that income.

"And this, with some important qualifications, is true as to certain kinds of public utilities. Take, for instance, a water plant or a gas plant. This serves a single community. As a rule it meets no competition in that service. The amount of its business is known or can be forecast with reasonable accuracy. Even matters of depreciation and such like have come to be pretty accurately understood. It is possible, therefore, to fix with some confidence the rates of such a utility when the value of the investment is known.

"With the railroads, however, this is entirely different for the reason that it seldom happens that a single railroad can be considered by itself. The greater part of the business of the railways of the United States is subject to competitive conditions of one sort and another which are largely controlling so that the rates of one are necessarily bound up with those of another. A moment's thought will show the extent to which this is true."

Also:

"* * * the railroads of this country are so bound up together that their rates are largely interdependent. It is impossible to shake a single railroad free from every other and fix its charges upon the basis of a fair return upon its fair value as you would in case of a gas or water plant. The rate established for one, of necessity, influences and frequently absolutely determines the rate of all, a fact which must never be forgotten in discussing this subject."

In the same speech, however, he adds:

"While, however, I wish to make it perfectly plain that the problem of establishing railway rates will not be solved by this valuation, I desire to say with even greater emphasis that the problem will be enormously simplified. It can be known with certainty whether the general level of rates is or is not too high, and in establishing the charges to be observed by a single carrier, even in fixing the rate upon a single commodity, it will be of much benefit to know the value of the property involved. Every railroad commissioner will join with me in saying that here is the only solid foundation upon which he can stand; that the determination of these values is indispensable to the just and intelligent administration of his work.

"While this valuation will be of incidental benefit to the investor, while it is essential to the work of the rate-making tribunal, it seems to me that its greatest immediate value is political. The state of the public mind towards our railways is such that this information is absolutely necessary."

Whether or not it is proper to base rates on the so-called "value" of the property is no concern of the Committee. The fact is that in many instances, including cases of railroad rates, the reasonableness of rates has been so determined, and, in making their decisions in disputed cases, the Courts have quite uniformly held that a public utility corporation is entitled to earn a "fair return" on the "fair value" of its property used in the public service.

Whenever the determination of the reasonableness of rates is reached in this way, it is necessary to value the property, and to value it in such a way that justice shall be done to the corporation and to the public. As this use of valuation of public utility properties was and now is prominently in the public mind, it seemed desirable to consider first the methods of valuation for this purpose. Hence, the Progress Report was limited to this field.

There seemed to be a failure to understand completely what the Committee proposed in its Progress Report, and there were those who contended that there could be but one value for any plant operated for gain, no matter what the purpose of the valuation. Further consideration by the Committee leads it to believe that much, if not all, of the misunderstanding is due to the unfortunate multiple meaning of the word value. In its own discussion the Committee has had difficulty in reaching conclusions, due to this cause. In its Progress Report the Committee adopted the current usage of the word value in accordance with the precedent set by Courts, authors, and legislatures. One of the most prominent of the authors of works on valuation has recognized the difficulties attached to the multiple meanings in the current usage of the word, but dismisses the subject with the statement that the substitution of other terms is not without difficulties.

After careful consideration, the Committee has concluded that the general use of a modified terminology would go far toward lessening the opportunity for misunderstanding, and therefore suggests that the use of the word "value" be restricted in general to its ordinary significance as defined by the Standard Dictionary: "The desirability or worth of a thing as compared with the desirability of something else," and has recognized the propriety of the use of other terms than "value" to express the bases on which purchase, rate-making, or the determination of the reasonableness of rates, capitalization, or taxation must rest. (See Glossary under VALUE.)

The Committee adopts this terminology except when it is necessary to use the terms "value" and "fair value" with the meanings attached to them by the Courts, in which case they will be enclosed in quotation marks.

The Committee has attempted in this report to cover the whole subject assigned to it, which requires a very extended report, even when it is limited to the general features of the subject. To cover all questions which arise in connection with valuation would be impracticable in a report by a committee of this Society.

The following preliminary statements may assist to an understanding of the discussions which follow:

1.—Although the report deals with the principles and methods of valuation, it lays stress on the fundamental principles. General methods are indicated, but little attention is given to detailed methods which necessarily vary under different circumstances.

2.—The discussions, unless otherwise stated, are confined to normal properties which are neither overbuilt, inadequate, nor improperly located.

3.—It is the view of the Committee that valuation should have its foundation in fact, and that the results obtained should be those which will be fair to the parties affected.

4.—The interdependence of methods of valuation and of regulation of public service properties must be recognized. Different methods of regulation may be adopted, which, taken in connection with the appropriate methods of valuation and consistently followed, will be fair to the parties affected. It is not, however, immaterial which of the fair methods are adopted, because one may be more closely in accordance with the law as defined by the Courts than another, and hence may be more capable of being carried out effectively.

5.—Where there may be two or more practicable and lawful methods of procedure, it is still desirable to aim toward uniformity and to select the most approved methods for general use, as this will tend toward simplicity and the avoidance of that confusion of thought and action which occurs when such uniformity does not exist. The methods

recommended by the Committee are those which, all things considered, are in its judgment most desirable for general use.

6.—The various elements which enter into the valuation of a property are frequently interdependent, and equitable results can be obtained only by a recognition of this fact.

7.—As indicated by the preceding paragraphs, a sharp distinction should be made between what may be done now under present laws and what may be done under future legislation and continuous commission control. The recommendations applying to present conditions should not be confused with those which can become practicable only with such legislation and control.

8.—The Committee has devoted the major portion of this report to a consideration of principles and methods which should govern in the valuation of the physical property plus development expense, or, in other words, what it has cost or would cost to create the property and to create the business. The valuation so determined does not cover all the elements of value which should receive consideration from the Courts and the various regulating bodies; therefore, a portion of the report is devoted to a discussion of intangible values and to other matters which may in many cases have an important bearing in the final determination of "value".

9.—Until the science of valuation and the adoption of sound accounting methods have advanced much further than at the present time, it is probable that different methods will have to be used in different cases to produce fair results, and special cases will always continue to arise which require methods adapted to them. The aim, however, should be toward uniformity.

10.—In questions relating to valuation, interest is an important item which should always be considered, and when interest is mentioned in this report it means interest compounded annually.

The valuation of public utilities has obtained special importance in recent years, and most of the literature relating to this subject has been issued within the last sixteen years. The principles and methods involved are now being carefully considered by many public service commissions and the Courts, as well as by engineers, lawyers, and committees of various societies having to do with public utilities. The subject is still in the developmental stage. Until recently, there were no engineering or legal works devoted exclusively to the valuation of public service properties, but since 1911 several important and valuable books on this subject have been published.*

* See "Valuation of Public Service Corporations," by Robert H. Whitten, New York, 1912 and 1914, a comprehensive work in two volumes in legal form, which contains a discussion of the various principles involved in the valuation of the property of public service corporations, and is replete with extended quotations from the opinions of the Courts; also, the following: "Valuation of Public Utility Properties," New York, 1912, and "Value for Rate-Making," New York, 1916, by Henry Floy; "Public

The Committee, in preparing this report, has carefully considered the views expressed in these recent works and in the many written discussions on the Progress Report.

Utilities, Their Cost New and Depreciation," New York, 1913, and "Public Utilities, Their Fair Present Value and Return," New York, 1915, by Hammond V. Hayes; "Principles of Depreciation," New York, 1915, by Earl A. Saliers; and "Public Utility Rates," New York, 1916, by Harry Barker.

See also Bibliography to July 16th, 1913, containing 61 pages, prepared in the Library of the American Society of Civil Engineers, under the direction of the Secretary, at the request of the Committee, *Transactions*, Am. Soc. C. E., Vol. LXXVI, December, 1913, p. 2133. This bibliography, together with an additional 72 pages, bringing it up to December 23d, 1915, has been published by the American Electric Railway Association.

CHAPTER II.

FUNDAMENTAL PRINCIPLES OF VALUATION.

A fundamental principle of primary importance is that a valuation shall be made so that it will be fair to all parties affected.

So long as it is desired that public service corporations and not government shall provide the utilities required by the public, it will be necessary, in the exercise of public regulation, to use principles and methods of valuation which, when properly applied, will attract the capital necessary for building new properties, for extending old ones, and for rendering satisfactory service.

Under normal conditions, the investor is induced to create new property by the prospect of obtaining a fair return on the amount of his investment*, and such investment is a fair basis for valuing such new property, but is not necessarily the "value".

Not many years ago, it was very common to value public service property by capitalizing the net earnings, and though the sum thus obtained may be a proper element for consideration under some conditions in the valuation of a property, it is manifestly not a proper basis on which to predicate reasonable returns.

The fundamental principles involved in the valuation of a new property are necessarily different in some respects from those involved in the valuation of an old one, because a new property, which has not begun to earn or to have the value of its parts affected by appreciation or depreciation, stands in a different position from an old one which has been in operation and earning for many years, and has many parts which may have appreciated or depreciated in value. Moreover, in the case of an old property, valuable property or rights may have been acquired or lost, without the payment or receipt of money therefor, as a result of time or through the failure of the public or the owner of the property to assert their authority. Property or rights so gained or lost affect the valuation materially, and a failure to recognize them would be inequitable to the present owners of the property and to the public.

A more extended statement will be given of the fundamental principles involved in the valuation for various purposes of these three classes of property, namely:

New properties;

Old properties under commission control from their inception;

Old properties which have not been subject to continuous regulation.

* The word, as used here, is intended to mean the reasonable and proper investment for creating the property, and not a reckless or improvident investment.

Valuation of New Properties.

If a new property, just ready for operation, is to be valued in connection with the determination of fair return, then, because working capital will be required, unfinished work must be completed, and development expense incurred, a reasonable and proper basis for what the Courts have called "fair value" is the actual investment in the property devoted to public use plus an estimated sum for working capital, final completion, and development expense, the word "investment" being defined, as in this report, to include not only the outlay of money but also the money value of services and other considerations involved. Such a basis is the most rational one to use in this connection, because a fair return on such a sum, would be a fair return on the investment, and this is what is needed to attract capital to such properties.

If the same property, just ready for operation, is to be valued for public purchase or in connection with condemnation proceedings by a public body, such as a municipality, the public purchase base of a successfully constructed property should be the actual cost, including the money value of services and other considerations involved.

A valuation of the same new property for capitalization should be determined in the same way as the return base, except that all parts of the property, whether devoted to the public use or not, should be included.

A valuation for taxation of a public service property, whether new or old, must accord with the laws of the State in which it is situated, whether or not the laws are equitable, and, where not governed by such laws, should, to make it equitable, be fixed at a sum consistent with the valuation of other property for taxation.

Valuation of Old Properties Under Commission Control from Their Inception.

Some of the basic principles involved in the valuation of old properties can be discussed best by taking a hypothetical case of a normal, well-established property, operating without competition and under commission control as to rates, methods of accounting, etc., from its inception. It is assumed that such a commission would have acted throughout the life of the property in accordance with the basic principles which should govern in such a case. Some of these are:

(*a*) The owner of the property is entitled to reimbursement through the earnings for all current expenses for operating the property and maintaining in good condition the units of which it is composed, including the amounts paid for taxes.

(*b*) The owner of the property is entitled to an allowance sufficient to provide for the net depreciation in the value of all units of physical

property, whether resulting from decay, wear and tear, or other causes, the amount of such depreciation allowance to be sufficient to pay for all such property units by the time they cease to have value.

(*c*) The owner of the property is entitled to a fair return on a "fair value" of the property, and such return should include, not only the ordinary rate of interest for the use of well-secured capital, but in addition a profit commensurate with the risks incidental to the investment.

(*d*) If, during the early years of operation, before the property is tuned up and the business developed, it is impracticable, as generally is the case, to earn the current expenses (*a*), a suitable depreciation allowance (*b*), and a fair return (*c*), the owner of the property should be compensated in some way for the loss during the early years.

The first of these basic principles (*a*) is universally recognized.

The second (*b*) does not define whether the depreciation allowance shall be annual or otherwise, but the decision of the United States Supreme Court in the Knoxville case supports the equitable principle that the allowance for depreciation should be earned annually and should be of sufficient size to keep the investment intact. A portion of the decision is as follows:

"* * * the company is entitled to earn a sufficient sum annually to provide, not only for current repairs, but for making good the depreciation and replacing the parts of the property when they come to the end of their life. The company is not bound to see its property gradually waste, without making provision out of earnings for its replacement. It is entitled to see that from earnings the value of the property invested is kept unimpaired, so that, at the end of any given term of years, the original investment remains as it was at the beginning."

The third basic principle (*c*) is applicable to normal properties and especially to those not subject to competition, and is in accordance with the general view which has been expressed by the United States Supreme Court for many years, namely, that the owner of a property is entitled to a fair return on the "fair value" of the property.

The fourth basic principle (*d*) can be applied in practice either by increasing the "fair value" of the property by the sum of the deficiency of earnings in the early years, with interest, or by allowing higher rates of return in subsequent years to offset the early deficiency. This subject is further discussed under the head of "Development Expense".

Valuation of Old Properties Which have not been Subject to Continuous Regulation.

The basic principles (*a*), (*b*), (*c*), and (*d*), given on the preceding pages, are important in connection with old properties not subject to

continuous regulation, but there is another basic principle already referred to, relating to such property, which in many cases makes the sum representing the sacrifice by the owner an inequitable basis of "fair value". This is:

(*e*) Valuable property or rights may have been acquired or lost by the owner of a public service property, as a result of time or through the failure of the public or the owner to assert their authority.

A failure to recognize such property or rights in a valuation at the present time would be unfair to the present owner or owners of the property or to the public.

The basic principle (*e*) may apply to many features of an old public service property, but two illustrations will indicate what is intended.

Years ago, in the absence of restrictions on rates, a public service corporation may have had very large earnings, and, after paying out adequate dividends, may have had a large surplus, which it expended in increasing and improving its property. Such action was then regarded as commendable. If the public for many years has neglected to exercise its right to regulate rates, it is only just and equitable that the increase and improvement in the property thus created should be recognized, and that the present-day owners should not be penalized for this neglect.

As an instance of a loss by the owner of an old property, he may long ago have neglected to charge rates sufficient to maintain his investment intact, with a resulting diminution in the value of his property. The public, many years afterward, could not be expected to make good the deficiency of former years. This is the view taken by the United States Supreme Court in the Knoxville case, where it states:

"If, however, a company failed to perform this plain duty and to exact sufficient returns to keep the investment unimpaired, whether this is the result of unwarranted dividends upon over issues of securities, or of omission to exact proper prices for the output, the fault is its own. When, therefore, a public regulation of its prices comes under question, the true value of the property then employed for the purpose of earning a return cannot be enhanced by a consideration of the errors in management which have been committed in the past."

The foregoing discussion is based chiefly on grounds of equity, but it is also true that the Courts recognize as a general rule that it is the present value of property which should be used, and not its cost.

Where the sum representing the sacrifice by the owner cannot be accepted as a basis for valuation, it is necessary to find other bases, and a discussion of these and the fundamental principles in each case will be found in the chapters headed "Original Cost to Date" and "Cost of Reproduction".

CHAPTER III.

PHYSICAL PROPERTY TO BE INCLUDED IN VALUATION.

The physical property to be included in valuation varies in different cases with the use to which the valuation is to be put and the law governing the case. It is desirable to cover the entire property, placing different classes in separate schedules, so that full information may be available to the Court or commission having the final decision as to the property to be included.

The most important questions which arise in making schedules are those which ask whether, and to what extent, property not devoted to the public use, property retired from service, temporary works, donated property, leased property, working capital, and securities owned shall be included. Is it proper to exclude a part of the total value of works on the ground that they have been built of a size in excess of that required for the service? Is the title to a property a controlling feature in determining whether or not it shall be included in the schedule? All these questions will be discussed in this chapter.

Used and Unused Property.

It is the well-established rule of the Courts that when a valuation is made for the purpose of rate regulation, only that property is to be included which is devoted to the public use or is used for the public convenience. In a valuation for capitalization, it is obvious that all the property should be included. In the case of condemnation of a property which is taken over by the public authorities, all the property condemned would be subject to valuation, and according to law every element of its value should be included.

The opinion of the United States Supreme Court with regard to the property to be included in valuation for rate regulation is shown by the following brief quotations from decisions, covering the period from 1898 to 1913:

"The fair value of the property being used by it for the convenience of the public." "What the company is entitled to ask is a fair return on the value of that which it employs for the public convenience." (Smyth *v.* Ames, 169 U. S., 466, March 7th, 1898, page 546.)

"The then value of the property actually used for the purpose of supplying water." (Stanislaus County *v.* San Joaquin and King's River Canal and Irrigation Co., 192 U. S., 201, January 18th, 1904, page 213.)

"The fair value of its property devoted to the public use." "The value of its property actually used for the public." (Willcox *v.* Consolidated Gas Co., 212 U. S., 19, January 4th, 1909, page 50.)

"The basis of calculation is the fair value of the property used for the convenience of the public." (Minnesota Rate Cases: Simpson *et al. v.* Shepard; Same *v.* Kennedy; Same *v.* Shillaber, 230 U. S., 352, June 9th, 1913, page 434.)

In view of these decisions, it is clear that the law does not provide for the inclusion of unused property in a valuation for the purpose of rate-regulation, but there must necessarily be much latitude in the determination of the property to be classed as "used" and "unused". Although a few of the discussions by the Courts indicate a tendency toward the exclusion of all property not "actually used", in cases of doubt both Courts and commissions have in practice favored including rather than excluding property.

Clearly it is a narrow construction of the law to claim, as has sometimes been done, that all property not actively in use at the time of the valuation should be excluded. A broader policy is desirable, both in the interests of the owner of the property and of the public. The property considered to be devoted to the public use, and therefore to be valued, should include, not only that in active use in the every-day operations, but that which is properly and reasonably held in reserve to insure the sufficiency and continuity of the service.

In general, it is not proper to apply any arbitrary rules excluding property temporarily out of use. Railroad equipment may be stored during periods of depression; snow-plows and flangers are in use only a small part of the time, and thousands of other cases might be cited of property not actually in service at the time of the appraisal, but useful, and essential as a part of the equipment of the property. In like manner, the duplicate pumps in a water-works, and reserve power units of all kinds, are essential to the proper operation of the property and necessary in times of emergency, although not actually used any considerable proportion of the time. No rule of valuation which excluded such property could be sustained by sound reasoning, as the very life of the service depends to a large extent on sufficient reserve to tide over emergency or peak of business. Such property should be included in regular schedules.

Recognizing that the erection of manufactories and other buildings, the opening of new streets, the laying out of parks, and the making of other customary improvements in the neighborhood of public utilities, as well as increases in the value of adjoining property, will make the future acquisition of lands for the expanding needs of such public utilities difficult and expensive, if not impossible, it has been customary for public utilities to exercise foresight in the purchase of surplus land at crucial points, and in the opinion of the Committee it is in the interest of both the owner of the property and of the public that such land purchased in good faith and held in reserve for future use

should be included in the valuation, even though portions are for a time not in active use.

The following extract from a decision of the New York Public Service Commission for the Second District, in a rate case, is quoted as an instance of what appears to be a rational treatment of the problem of determining what portion of certain lands should be included as used property (Buffalo Gas Co. *v.* City of Buffalo, 3 P. S. C., N. Y., 2 D., 553, February 4th, 1913, pages 578-579):

"All of the land at the Genesee Street plant should be treated as in the public service. The contention of the city that a certain parcel next to the canal is not in the public service should not be allowed. It is not in fact used at this moment, but it is directly adjacent to the generating plant of the company, and with any growth in the business would undoubtedly be needed; and justice and fair dealing do not allow for a moment the quantity of land to be scaled down to the lowest point possible under present circumstances. The company is fairly entitled to a reserve of land of this character at this location * * *.

"At East Ferry Street there are 5½ acres of land. The only use it has in the public service is that of a holder station; 5½ acres for this purpose is not shown by any evidence in the case to be warranted. As a matter of fact, but a portion of this land is used for that purpose; and there is no evidence showing that more will be required for public use within a reasonable time in the future or in fact at any time. An allowance of one-half of this land as being in the public service is liberal to the company.

"At Forest Avenue there are two parcels of land separated by the tracks of the New York Central railroad. The smaller tract is rented for and used as a coal yard, and has no connection whatever with the public service. A considerable portion of the larger tract next to the water is not in fact used in the public service at the present time. The holder and engine-house are situated at one end of the lot, and some small cheap buildings at the other end which are not used for gas purposes. Owing to connection with the street, location of piping, etc., it is believed that it may not be unreasonable to treat the whole tract as being in the public service."

Although the Committee believes that the law relating to used and unused property should be interpreted liberally, as above indicated, it recognizes that, were it the policy to value all land which the owners of a public utility might purchase, on the ground that it would be needed for future use, such policy might lead to speculation in land to be held for a time at the expense of the public and subsequently sold at a profit, without having served it.

A very narrow view is sometimes taken on the area of land to be included in a valuation for rate regulation, as for instance in the case of a recent railroad rate investigation where it was claimed that there should be excluded from the valuation (*a*) all lands owned in terminals and large cities not actually in present use and covered with tracks,

buildings, or company materials, and (*b*) all portions of the right of way not actually included within the slopes of cuts or fills.

The width of a railroad right of way is determined by the depth of excavations or embankments, the necessity of securing materials for forming the banks, the need of providing room for the operations of contractors, as well as by consideration of the necessities of operation.

Another case called to the attention of the Committee is an objection to the inclusion of lots in a city making a right of way 225 ft. in width, while the present use of the property is to support a double-track bridge 65 ft. from the top of rail to ground surface, the present structure covering the central 50 ft. In this case the entire strip was amply justified on three grounds: (1) that it was all needed for the construction and maintenance of the present large timber structures and that any less would give insufficient room; (2) that the land owned was barely sufficient to support an earth embankment if that form of permanent structure should finally be determined upon; and (3) that the land was necessary for the protection of its existing structure from encroachment of buildings which would create a fire hazard.

It is the opinion of the Committee that, in a valuation for the purpose of rate regulation, there should be included, not only the lands actively in use and covered by the construction, but such additional area as is necessary to permit the economical construction of the works, to safeguard the property and protect it from such encroachments as might interfere with its operation or create an extra hazard and to provide for permanent in place of temporary construction. Good business judgment in the acquisition of land frequently requires the purchase of a whole parcel of land where the greater part of the parcel is required for the purposes of the utility. All the land thus acquired should be included in a valuation.

If a 100-ft. strip of land constituted a proper width for constructing a certain single-track railroad and permitted the construction operations to be handled economically and properly, no part of that right of way should be excluded on the ground that the embankments only occupied space equivalent to 41 ft. average width.

Equally important is the question of inclusion or exclusion in valuation for rate regulation of lands held in reserve for future extensions.

In very many, if not most, cases where this question is raised it will be found that a tract of land has been acquired sufficient to provide a suitable site for the proposed plant and to provide for such extensions as are reasonably likely to be made in the near future. It is poor business judgment to build a gas plant, an

electric plant, a railroad shop yard, or other like property, on land just sufficient to hold the buildings and other improvements immediately necessary, without reasonable provision for expansion. The history of all properties that have been built in response to reasonable demand for their services has been a history of growth, development, and expansion. Good business policy would provide for this expansion so far as it can be reasonably anticipated, and all property should be included which is not in excess of a reasonable amount for development of the business over a reasonable period of time in advance of the valuation. Such a determination is not a matter of pure speculation. An investigation into the history of the growth, expansion of business, and expansion of physical property of the company, together with a consideration of existing conditions at each site, should easily determine the reasonableness or unreasonableness of the inclusion.

A very mooted question as to the inclusion of land is found in the case of a company which has bought such property, disconnected from existing works, for future use and development. Often many large holdings are acquired some time in advance of development, at prices much lower than would prevail if bought when the need was pressing and the transaction forced. The general policy of the Courts appears to have been to exclude such holdings in cases relating to rate regulation, unless it was apparent that the property was to be used in the near future.

While the rulings of the Court in regard to the exclusion of such reserve properties, or properties which have not yet come into use, may be justified on the ground that the company may defer its purchase unless it is willing to take the risk that the advance in value will furnish sufficient compensation for holding the property, and while it is true that there are cases in which to include all such properties would lead to abuse, the Committee is of the opinion that there are other cases in which it is very desirable, in the interests of economy and efficiency, that corporations should anticipate the future needs of the service, and that the reserve properties held to meet such future needs should be included in valuation. Instances might be: a distributing reservoir site on the top of a hill, purchased before the hill property is sub-divided into streets and house lots; a dock site on a deep-water harbor for the future use of a railroad; and water rights acquired when they can be obtained at small cost, lest by reason of later developments the company may have to pay heavy consequential damages or substantially monopoly prices for them, or even be unable to obtain them if they have been appropriated by others, the last instance being particularly applicable to the semi-arid and arid regions in the Western and Southwestern United States.

The foregoing views may be less applicable when the valuation of the land purchased for future use is based on the reproduction cost, than when based on original cost, because, if the public is required to pay an increased rate on account of the inclusion of land which is not used, and the increase in the value of land as shown by the difference between reproduction and original cost inures to the company, an inequitable result may be reached.

In the actual work of making a valuation, there are many cases in which there would be no difficulty in reaching a decision as to whether or not a given property should be classed as a part of that used for the convenience of the public. For instance, property used for the commercial mining of coal, although owned by a railroad company, obviously should not be included in a valuation of the property of that company devoted to the public use, but there are other cases in which it is more difficult to decide. Among these may be mentioned office buildings owned by public service companies, which are rented wholly or in part to the public, property temporarily leased to others, pending its active use in the service of the public, and hotels and parks owned by railroad companies. Matters of this kind generally have to be settled by a consideration of the specific cases, on the basis that properties which are a part of the operating plant of the company or are being used for the convenience or benefit of the public should be included. When so included, the income arising from the operation of these properties should be duly credited.

Retired or Discarded Property.

Closely allied with, and in fact a part of, the unused property is that which has been used by a public service company and has been retired or discarded prior to the time of the valuation.

Under the rulings of the Supreme Court, and in accordance with many rulings of other Courts and of commissions, such property would be excluded from a valuation. There are cases in which such rulings seem to be opposed to fair dealing to the owner of the property abandoned. Instances of this kind may be found where a telephone or electric light company is suddenly ordered to remove all overhead wires and place them underground, before the company has had an opportunity to charge off the cost of the overhead wires.

Under public regulation at the present time, due account is sometimes taken of that part of the cost of the discarded property which has not been charged off, and the public service company, instead of being required to charge the remaining cost of the discarded property at once to operating expense, is permitted to charge it to a suspense account for the purpose of distributing the loss to the operating expense of a succeeding period of years.

The Interstate Commerce Commission, in its uniform system of accounts for telephone companies, referring to such losses, states ("Uniform System of Accounts for Telephone Companies", First Issue, effective January 1st, 1913, page 68):

"Losses of this sort may be due to the requirement by lawful authority or public necessity of improvements involving the abandonment of a considerable portion of plant and equipment before it has attained its normal life in service, or to an extraordinary casualty entirely unforeseen and unprovided for. The original cost of the property so abandoned or destroyed should be credited to the fixed capital accounts in which it was carried, and such portion of the cost as may be authorized by the Commission may be charged to the suspense account, the remainder of the cost, less any salvage, being charged out as elsewhere provided in case of retirements of property. The suspense account so raised should be credited and account No. 609, 'Extraordinary Depreciation', debited monthly with such an amount as will, through its regular application, amortize the amount of the loss at the end of the period designated."

Similar provisions occur in the systems of accounts for other carriers.

In a few instances public service commissions have permitted the inclusion of discarded property in the valuation for a term of years. As an instance, a decision by the California Railroad Commission in a rate case is quoted (Solari *v.* Tuolumne County Electric Power and Light Co., 3 Cal. R. C. R., July 29th, 1913, pages 1051-1052). The valuation was that of an electric plant.

"It seems fair, however, to permit the defendant during each of the ensuing ten years to collect rates high enough to permit it to charge off such sum on its books that by the end of the ten years the principal so charged off, together with the interest, shall have amounted to the entire value of the line at the present time. I believe that it will be very liberal on the part of the rate-fixing authorities to permit this to be done."

Where plant units have been worn out in service and definitely abandoned, or by reason of the reconstruction of property, parts have been abandoned, and are not only unused but not likely again to be used, such units and parts should appear either in a separate schedule of retired or discarded property, or such full statement of the conditions should be made as will definitely fix the status of the units or parts.

There is another class of property which, even though out of use, should not be excluded from a valuation on the ground that it is retired or discarded property. This includes the temporary works required for the construction of the permanent items of physical property, as, for instance, the temporary falseworks used to support a bridge during its construction, the coffer-dam required to keep the

site of a dam or a bridge pier free from water, or material and labor of preliminary track surfacing required for the protection of rails from injury under construction traffic prior to the commencement and completion of permanent ballasting. Although such temporary works are discarded after the completion of the permanent works, their cost is clearly a part of the cost of the permanent works, and is properly includible when determining unit prices.

Similarly, the cost of temporary works which are necessarily built in connection with the construction of permanent works, as, for instance, the cost of a pile bridge built in advance of the completion of a permanent bridge for the purpose of expeditious and economic construction, should be included in the cost of the permanent bridge.

In accordance with the same general principle, it seems proper to include in a valuation the cost of temporary works built to furnish service to the public at an earlier date than it could be furnished by the permanent works. For instance, a temporary water-works pumping station is sometimes provided for use during the construction of a permanent pumping station. Such works may be advantageous to the public as well as to the owner of the public utility, and their cost may be regarded as a part of the cost of construction, although due allowance should be made for receipts from operation.

Excessive Size or Capacity.

Somewhat allied to the question of used and unused property is that of excessive size or capacity. It is sometimes claimed that the public should not be required to pay rates on works having a size or capacity in excess of that required for the purposes of the community served. Rulings on this feature of valuation have been made by the Courts and commissions in several instances.

Judge Savage of the Maine Supreme Court used this illustration (Brunswick and Topsham Water District *v.* Maine Water Co., 99 Maine, 371, Dec. 14th, 1904):

"Suppose that a five-hundred horse-power engine was used for pumping when a one-hundred horse-power engine would do as well. As property to be fairly valued, the larger engine might be more valuable than the smaller one, yet it could not be said that it would be reasonable to compel the public to pay rates based upon the value of the unnecessarily expensive engine."

Judge Pitney, of the New Jersey Chancery Court, diminished the valuation of a water plant by nearly $130 000 out of a total of $1 400 000, on the ground that a 36-in. main was used where a 30-in. main would have been sufficient, and because a dam was made of excessive width for present purposes in order that it might be raised subsequently. (Long Branch Commission *v.* Tintern Manor Water Co., 70 N. J. Eq., 71, November, 1905.)

In most of the commission decisions stress is laid on the necessity of providing adequately for future needs in order that satisfactory service may be furnished continuously, and it is stated that it is not desirable in the general interest of consumers to discourage a reasonably liberal provision for the future.

The Canada Board of Railway Commissioners, in the application of the City of Montreal for the reduction of telephone rates, made the following statement, October 28th, 1912:

"There is no question that preparation for future needs is one of the incidents of the proper management of a public utility corporation. If it is to allow demands for service to pile up and then make an expansion only after the urgency is sufficiently great, the public will be subjected to the disadvantage of delay in obtaining service, and at the same time the piecemeal method of construction this will necessitate will undoubtedly add to the cost of the plant. A comprehensive system of preparation for future needs must be followed if there is to be proper expansion. Undoubtedly this will normally lessen the cost of construction to the company. It is also of advantage to the public using telephone service because it gives a decreased basis on which earnings are to be obtained."

In the case of the Des Moines Water Co. *v.* City of Des Moines, the Master, in his report of September 16th, 1910, says:

"* * * the company has the right to anticipate the growth of its business and to be allowed a proper return on a plant of sufficient capacity for such growth."

The Massachusetts Gas and Electric Light Commission, in the Haverhill gas rate case, decided December 31st, 1912, made this statement:

"The Board can not, in the general interest of consumers, discourage the reasonably liberal provision for the future which this company seems to have made."

It is the judgment of the Committee that there should not be a reduction in the valuation on account of excessive size or capacity, except when the excess is so great as to be clearly unreasonable and is the result of not using proper foresight. The opinions of engineers and others engaged in building public service property differ materially as to the length of time for which it is economical and proper to make provision under the different circumstances, and property built with reasonable foresight should not have its value diminished because expectations have not been fulfilled by subsequent developments.

If the opposite course is pursued, corporations may be deterred from making wise provision for the future, thereby increasing the hazard of the investor, probably increasing the ultimate cost by reason of premature retirement, duplication, or piecemeal construction, and hence ultimately increasing the cost of service to the public.

Donated Property.

The Committee believes that land or other property which has been voluntarily donated by the public or by private parties to a railroad or other public utility should be included when determining the reproduction cost, on the same basis as land and property otherwise acquired.

It is especially true that property donated many years ago should be so included, because the company which has held such property for a long term of years, with the acquiescence of the public, has acquired full rights therein, even if it did not have them originally. Such donations were generally made because companies could not profitably furnish a demanded service without such assistance. The donations were necessary to prevent the proposed project from becoming a "losing venture".

There are some instances in which a company has the title to a given property which should not be included in the reproduction cost, and, conversely, other instances in which a company has no title to a given property which should be included in such cost. This subject is discussed on subsequent pages of this chapter, under the heading "Title to Property not Conclusive".

Leased Property.

In the case of leased property, either the property itself or the lease should be valued, as circumstances may dictate.

When a valuation is made for the purpose of rate regulation, it is usually customary and proper to include in it property owned or leased for long-term periods and used for the convenience of the public, although the valuations of the owned and leased property should be kept separate for the information of the Court or commission. Short-term leases may be given a positive or negative value, according to whether they represent prospective profit or loss.

When a valuation is made for the purpose of capitalization, property leased to and not owned by the corporation whose property is being valued should be excluded, although there may be exceptions to this rule in the case of leases which for any reason are practically equivalent to ownership.

When a valuation is made as a basis for selling the property of the operating company, the value assigned to leaseholds should depend on the duration, character of control, and advantages or disadvantages accruing to the lessee by reason thereof.

The foregoing statements are chiefly applicable to leases made between public service corporations, and may not apply to the many instances in which minor leases are made between a public service corporation and private parties.

Title to Property Not Conclusive.

When a valuation of a public service property is made, it is frequently necessary, in order to be fair to all parties interested, to depart from the usual rules relating to ordinary private property, and to include in the valuation more or less property situated on land to which the owner of the public utility has no title, and, on the other hand, to exclude property situated on land to which he has a title.

The proper general rule, subject to exceptions, appears to be that the owner of a public utility is entitled to have included in the valuation of his property all those works for which he has been required by law or necessity to pay the cost, including in this class also property voluntarily donated, and that there should be excluded all those works for which other public service companies, the public or the users have been required by law or necessity to pay the cost.

For instance, it would be unfair to require a railroad company, as a part of the work of abolishing grade crossings, to raise highways in order to furnish suitable approaches to an overhead bridge, and to exclude the embankments thus formed from a schedule of the company property to be valued, on the ground that the company did not have the title to the land on which they were located, or for the same reason to exclude from the schedule in the valuation of street railway property the pavements which the company may have been required to lay in connection with its tracks.

Similarly, in valuing a water or gas property, it would be unfair to include in the schedule those service pipes from the mains to the street line that have been paid for and are maintained by the consumers of the water or gas, unless contractual obligations shall determine otherwise.

The pavements over the mains laid by gas and water companies furnish further instances of property to which the companies have no title, but it is generally conceded that the companies are entitled to have included in an estimated cost of reproduction the cost of removing and replacing such pavements as were actually removed and replaced by them when laying the mains.

The propriety of the inclusion or exclusion of the cost of removing and replacing the paving over mains not actually removed and replaced, is discussed in the chapter on reproduction cost. There is, however, a difference of opinion as to whether the cost of removing and replacing pavements laid at the expense of the public after the mains were in place should be so included. In accordance with the rule above stated, they should not be included, though upon a strict interpretation of reproduction under present conditions, the pavements would have to be cut, and if they can be shown in fact to increase the value of the pipe system, and the property as a whole,

this increase in value may be considered. In the most recent decision of the U. S. Supreme Court, however, the Court has held that they did not in fact increase value in the case under review.

The more recent and important Court and commission decisions exclude from "fair value" those pavements and other items laid or constructed without expense to the company.

In 1907, the decision of District Judge Hough, of the Federal Court, in the Consolidated Gas Co. case (Consolidated Gas Co. *v.* City of New York, 157 Fed., 849, December 20th, 1907), included in "fair value" the increased construction expense of pipe systems over which pavements had been placed at the expense of the city. On appeal, the United States Supreme Court (Willcox *v.* Consolidated Gas Co., 212 U. S., 19, January 4th, 1909) did not take up the question of the inclusion of pavements, but concurred with the Court below to this extent:

"And we concur with the court below in holding that the value of the property is to be determined as of the time when the inquiry is made regarding the rates. If the property, which legally enters into the consideration of the question of rates, has increased in value since it was acquired, the company is entitled to the benefit of such increase. This is, at any rate, the general rule."

In 1912, District Judge McPherson, of the Federal Court, in the case of the Des Moines Gas Co. *v.* City of Des Moines (199 Fed., 204, August 21st, 1912), supported the exclusion by the Master of the reproduction cost of pavements laid at the expense of the city, thus taking a position diametrically opposite that taken by Judge Hough.

Upon appeal, this case went to the United States Supreme Court (238 U. S., 171, June 14th, 1915), which supported the attitude of the Master and of Judge McPherson regarding the exclusion of pavements laid at the expense of the city. Mr. Justice Day says:

"As to the item of $140 000, which, it is contended, should be added to the valuation, because of the fact that the Master valued the property on the basis of the cost of reproduction new, less depreciation, and it would be necessary in such reproduction to take up and replace pavements on streets which were unpaved when the gas mains were laid, in order to replace the mains, we are of opinion that the court below correctly disposed of this question. These pavements were already in place. It may be conceded that they would require removal at the time when it became necessary to reproduce the plants in this respect. The Master reached the conclusion that the life of the mains would not be enhanced by the necessity of removing the pavements, and that the Company had no right of property in the pavements thus dealt with, and that there was neither justice nor equity in requiring the people who had been at the expense of paving the streets to pay an additional sum for gas because the plant, when put in, would have to be at the expense of taking up and replacing the pavements in building

the same. He held that such added value was wholly theoretical, when no benefit was derived therefrom. We find no error in this disposition of the question."

One of the modern decisions along these lines is that of the Court of Appeals of the State of New York (Kings County Lighting Co., People *ex rel. v.* Willcox, 210 N. Y., 479, March 24th, 1914). The New York Public Service Commission for the First District declined to include in a valuation of the property of the Kings County Lighting Company the pavement over its mains in cases where such pavements were not laid at the expense of the company.

The Appellate Division of the Supreme Court of New York reversed the determination of the Commission. The case was taken to the Court of Appeals, which reversed the action of the Appellate Division and sustained the ruling of the Commission. Judge Miller says (at pages 494-495):

"In determining the cost of reproduction, the Commission allowed $12 717 as the cost of restoring the pavement as it existed when the mains and service pipes were laid in the streets. The relator claimed an allowance of at least $200 000 for the cost of restoring pavements subsequently laid, on the theory that the cost would have to be incurred if the mains were to be laid to-day. But the new pavements in fact added nothing to the property of the relator. Its mains were as serviceable and intrinsically as valuable before as after the new pavements were laid. The controlling considerations under the preceding point also determine this. The rights of the public are not to be ignored. The question has a double aspect. What will be fair to the public as well as to the relator? (Smyth *v.* Ames, *supra.*) Should the public pay more for gas simply because improved pavements have been laid at public expense? It is no answer to say that the new expensive pavements suggest improved conditions which, though adding to the value of the plant, will not, by reason of the greater consumption, add to the expense per thousand feet of the gas consumed. The public are entitled to the benefit of the improved conditions, if thereby the relator is enabled to supply gas at a less rate. The relator is entitled to a fair return on its investment, not on improvements made at public expense. It is said that the mains will have to be relaid. So will the new pavements, and much oftener. Both might possibly be relaid at the same time. The case is not at all parallel to the so-called unearned increment of land. That the company owns. It does not own the pavements, and the laying of them does not add to its investment or increase the cost to it of producing gas. The cost of reproduction less accrued depreciation rule seems to be the one generally employed in rate cases. But it is merely a rule of convenience and must be applied with reason. On the one hand, it should not be so applied as to deprive the corporation of a fair return at all times on the reasonable, proper and necessary investment made by it to serve the public, and on the other hand it should not be so applied as to give the corporation a return on improvements made at public expense which in no way increase the cost to it of performing that service.

"The Appellate Division felt bound by the decision of the United States Circuit Court in the Consolidated Gas Case (157 Fed. Rep., 849), and it is true that such an allowance was made in that case. But the United States Supreme Court held in that case (212 U. S., 19) that the rate established was not confiscatory, and did not pass on the propriety of that allowance. What was said in the opinion on the subject of present value was merely a general statement having no necessary relation to the question now under consideration."

The more recent decisions of the California, Illinois, Indiana, Maryland, New Jersey, New York, Washington, and Wisconsin Commissions have excluded from "fair value" the cost of pavements laid without expense to the company.

This subject is discussed further under the caption "Shall Present or Original Physical Conditions Govern?" on pages 1363 to 1370.

Under special laws providing for the creation of some public utilities, of which elevated railroads and large storage reservoirs are examples, it is required that the owner of the utility shall pay incidental damages on account of property injured, but of which no part is taken. Such damages are an important factor in the original cost of a property, and a corresponding item should appear in the reproduction cost, irrespective of the fact that the owner of the public utility has no title to the property in question.

Working Capital.

It is customary to include under the term "working capital" the amount of cash, materials and supplies provided for use in the plant but not yet forming a part of it, and other current assets which are essential for the proper maintenance, operation, and administration of a property.

There should be included in a valuation an amount of working capital sufficiently large, not only to meet the usual requirements, but to provide for emergencies.

Securities Owned.

Ordinarily, the valuation of property devoted to public use should not include securities owned or surplus cash not forming a part of working capital, except in instances where such securities and surplus cash are an offset, in whole or in part, for depreciation deducted from the cost of the property. The treatment of such cases is covered in Chapter VI, "Depreciation and Appreciation."

CHAPTER IV.

ORIGINAL COST TO DATE.

The term "original cost to date" is used in the Federal Valuation Act, and appears to have substantially the same meaning as the terms "original cost", "original cost plus improvements", and "actual cost".

In the absence of any generally accepted or well-defined legal meaning of this term, the Committee has defined it as "the cost of the original construction, plus all charges against capital proper, under approved accounting principles, for expenditures incurred thereafter, and minus all proper credits to capital for the cost of property which has been disposed of or otherwise retired".

Under this definition, the original cost to date of a property is the first cost* of the identical property units now in use, including overhead charges. This definition accords with modern methods of accounting, by which the cost of property retired is credited to the fixed capital account† to which it stands charged, or to some corresponding account, and the cost of property, added as a replacement, or otherwise, is debited to the fixed capital account or other corresponding account; it seems, also, to conform more nearly than any other definition with the decisions of the Courts that property which has been retired shall be excluded (excepting its salvage value) when making a valuation.

In the case of properties built by present owners, original cost to date should agree with the book or accounting cost in most respects, if modern methods of accounting have been followed from the beginning, but, even with such properties, correct accounting in accordance with modern practice is rare, and book cost, even when the books have been well kept, may differ greatly from original cost to date, as above defined.

* The definition of cost given by the Committee includes "not only money outlay, but also the money value of services rendered and of other considerations involved".

† In "Uniform System of Accounts for Telephone Companies", as prescribed by the Interstate Commerce Commission, First Issue, Effective January 1, 1913, fixed capital is defined as "property, both tangible and intangible, which is devoted to the accomplishment of the principal purposes of its business", and it "consists of original capital, additions, betterments, and replacements".

Referring to replacements, which it defines as "the substitution of one building, structure, piece of equipment, or machinery for another which it has become necessary to retire, the substitute having substantially no greater capacity than the properly replaced", it provides the following method of accounting:

"The cost of the fixed capital retired should be credited to the fixed capital accounts in which it is carried and the cost of the fixed capital installed in place of fixed capital so retired should be charged to the appropriate subaccounts under account No. 101, 'Fixed Capital Installed Since December 31, 1912'."

Under the head "Fixed capital withdrawn or retired", it provides:

"When any tangible fixed capital acquired subsequent to December 31, 1912, is withdrawn or retired from service for any cause the amount at which it stands charged should be credited to the fixed capital account in which it is charged, and such amount, plus the expenses incident to the retirement, less the value of salvage, should be charged to account No. 102, 'Reserve for Accrued Depreciation—Cr.'"

One important difference between book or accounting cost and original cost to date has arisen from a former method of bookkeeping which is still in use for some classes of property, by which, when a plant unit is replaced by an identical unit, no entry is made on the books, and consequently the cost of the original unit is retained and not the cost of the succeeding unit.

For instance, if a pipe costing $20 per ton for material is replaced by one of the same size and weight costing $25 per ton for material, the cost at $20 per ton remains on the books. Similarly, if a plant unit is replaced by one of larger size or heavier weight, the cost of the additional size or weight is entered on the books at the prices existing at the time of the replacement, and added to the cost of the original unit, so that the new unit appears in part at one price and in part at another.

Difficulty in Obtaining Original Cost to Date.

The statement has frequently been made, by those dealing with the valuation of public service properties, that it is not feasible to obtain the original cost to date of most old properties, and this is undoubtedly true in most cases in regard to the older portions of such properties and to the overhead charges. The difficulty, however, has been magnified in some cases by the conception that original cost to date deals with the money paid for original property units which have been replaced, and not with that paid for existing units. In some cases much of the difficulty may be removed under the definition given by the Committee, especially in the case of short-lived property.

As original cost to date, with comparatively few exceptions, is not the book cost of the property but the cost of the existing items, it will be necessary as a rule to make a schedule of the various existing property items, in the same way that one would be made for determining the cost of reproduction; then reference would have to be made to the accounts, to ascertain the unit costs of the items.

It would seem that almost any system of accounts which was correctly kept, even if not based on modern accounting principles, should show the cost of those items which have been purchased in the last 10 to 20 years. The cost of longer-lived items may not appear on the books, or the books for the earlier years may not be available, especially if the properties have changed hands. In such cases, the only way in which the determination of original cost to date could be completed would be by estimating, from the best information which could be obtained, the unit prices existing at the time the property items were constructed or acquired.

In the case of an old property consisting mainly of long-lived items, it is seldom practicable to obtain the original cost to date, except for the additions made in recent years, and if such cost could be obtained it would have little value.

In every case where records of original costs of presently existing items are not to be had, an attempt to determine original cost to date becomes an estimate, the correctness of which will depend on the completeness and accuracy of existing historic data. The result is likely to be less inaccurate in the case of a recently built property than in the case of an old property, but in no case in which estimate must be resorted to can the result properly be called original cost to date.

Schedule.

To ascertain original cost to date, it is necessary, as a rule, that a schedule be made of the various existing property items in the same way that one would be made for determining the cost of reproduction. (See further discussion of "Schedule" on pages 1377 to 1380.)

Exceptional cases, in which a detailed schedule may not be necessary for all parts of a property, include those in which the whole or a part of a property has been built at so late a date that the original units are still in existence, and those other properties of comparatively recent date where the accounting has been such that additions and betterments are charged to the fixed capital account and the cost of property retired has been credited to this or a similar account. However, even in these cases, an inventory may be desirable for the purpose of checking the results obtained from the books. Under the most favorable conditions as to records, it may be necessary to make many adjustments in order to obtain correct results.

Costs—Unit Costs.

In cases where a schedule is necessary, the corresponding costs or unit costs are also necessary in order to complete the inventory. Whether these are the actual costs of units or groups of units, or the unit costs, will depend on the method of bookkeeping which has been used.

There may be many cases in which work which covers many items has been done by a contractor for a lump sum, in which case it may be necessary, in making the schedule, to group the items included in the contract and to place opposite them the total sum paid the contractor, together with all the incidental charges properly attributable to the work.

When practicable, however, it is preferable to keep the items on the schedule separate, or in groups of identical items of the same age,

and to apply unit costs, either given directly in the books or which may be determined from them, including in such costs the direct incidental expenses, such as inspection, freight, carting, storing, laying or placing, etc.

In the case of property units acquired or created long ago, it will be impracticable, as a rule, to obtain the costs or unit costs from the books, and in such cases the ascertainment of the original cost is impossible, and it would have little significance if it could be ascertained.

Overhead Charges.

The expenses to be included in overhead charges are discussed more fully under this head in the succeeding chapter relating to cost of reproduction.

In brief, however, they may be said to consist of the preliminary expenses of promoting, investigating, organizing, and financing, and the incidental expenses during construction, which may be classified under the heads of engineering, general expenses (including the administrative, legal and financial expenses, taxes and insurance), and interest.

When the detailed accounts giving the cost of a property are available, these items should appear in them, but in many cases no account may have been taken of the value of the services of those engaged in promoting and constructing the work, or proper allowance for interest on the capital, or the records may be in such shape as to defy analysis.

Bonds may have been sold at discounts. Under the ruling of the Interstate Commerce Commission, that proportion of discounts and commissions on bonds is to be included in capital which is represented by the proportion of the construction period to the life of the bonds. The remainders of the discounts and commissions are not to be considered as capital, but are to be amortized over the remaining life of the bonds.

The Committee believes that reasonable commissions for selling securities of any kind should be included as a capital charge, but that discounts on bonds over and above such reasonable commissions should be treated as a capital charge only in such proportion as the construction period bears to the life of the bonds, the remainder being amortized over the remaining life of the bonds.

After the construction period has ended and the regular operation of a property has begun, the method of accounting is frequently such that the salaries and expenses of the permanent engineering, administrative, and legal staff are charged wholly to operating expenses, although a part of the time of this staff is devoted to the construction of additions to the property, and should properly be included as a part of

their cost. Similarly, there is frequently a failure to charge to the proper account the interest during the construction of such additions. Adjustments should be made so as to include in the cost of such additions the overhead charges properly attributable to them. On the other hand, there may be occasion, when determining the overhead charges from the book accounts of an old property, to make deductions of such charges as are properly attributable to plant units which have gone out of use.

The statements in the last paragraph may invite the criticism that, if the method of bookkeeping is such that a part of the overhead charges for additions to the property has been placed in operating expenses, it has been paid for by the public and not by the company, and hence should not appear in a valuation of the property. In this matter the Committee makes a distinction between valuation and regulation, and takes the ground that in valuation the total cost of the property should be included, regardless of past methods of bookkeeping. It recognizes, however, that in continuous regulation, including the control of rates by a public service commission, there should be no duplications by charging items to both the capital and the expense accounts.

Development Expense.

The development expense actually incurred in connection with the tuning up and creation of the business of a property should be included as a part of the original cost to date. The subject is fully discussed in Chapter VII.

CHAPTER V.

COST OF REPRODUCTION.

The Theory of Reproduction.

Different Applications of Reproduction in Past Practice.—Cost of Reproduction is defined by the Committee as:

"The estimated cost of reproducing the property without deduction for the loss of value due to age or other causes."

The practice of those engaged in valuation work, from the beginning of such work up to the present time, has varied widely in the matter of determining the cost of reproduction. Some base such cost on existing physical conditions, others on historic conditions, and still others combine the two. Some engineers have included only those physical property units which were actually created in the construction of the property, that is, they have used historic conditions, as to items of cost, with present-day prices for labor and material. Others have used substitute units, or historic prices, or original instead of present methods of work, and still others have used original conditions, original prices, and original methods, in making an estimate of reproduction cost.

This failure of engineers engaged in valuation practice to agree on a uniform conception of reproduction has cast some doubt on the real worth of Cost of Reproduction as one of the measures of value.

The United States Supreme Court, in the Nebraska rate case, states the various matters to be considered in determining value, as follows: (Smyth *v.* Ames, 169 U. S., 466, March 7th, 1898).

"And in order to ascertain that value, the original cost of construction, the amount expended in permanent improvements, the amount and value of its stocks and bonds, the present as compared with the original cost of construction, the probable earning capacity * * * are all matters for consideration and are to be given such weight as may be just and right in each case."

This case has been cited in most valuation cases, and the use of the word "Reproduction" has been very general in subsequent decisions, although it is to be noted it is not used in the decision in Smyth *vs.* Ames. It is clear that the Courts in many cases have recognized the reproduction estimate as one of the most important bases for determining value (Louisville & Nashville R. R. Co. *v.* Railroad Commission of Alabama, 196 Fed., 800 (1912), Hon. Thomas G. Jones, District Judge, N. & M. D., Alabama).

"In reference to the question of value with the view of rate regulation, the most reliable test ordinarily is the cost of reproduction of

the road as it exists. I say 'ordinarily' because there may be instances, which is not the case here, where by reason of paralleling the road by a new road, and diverting its business or from other causes, its value may be far less than what it will cost to reproduce it as it is at the time of the inquiry. The original cost of the road may in some cases reflect light on, or even determine, the present value, as when it is of very recent construction. But ordinarily it is of little assistance in that regard, since many items of value may be donations by the government or by individuals * * * or the road may have been built long before the period of inquiry at greatly less or greatly higher prices than those prevailing at the time of the inquiry. * * * Therefore, while looking at all collateral matters reflecting light on the subject, the court regards reproduction cost as the final test of present value. * * *"

In the Knoxville decision it is stated that:

"The cost of reproduction is one way of ascertaining the present value of a plant."

In this and practically all other cases in recent years, in which the values of old properties were under consideration, the evidence relating to cost which has served as a basis for determining value has been the reproduction cost.

In the case of the Consolidated Gas Co. *vs.* City of New York (157 Fed. Rep., 849, December 20th, 1907), District Judge Hough says:

"The complainant demands a fair return upon the reproduction value thereof, which is the same thing as the present value properly considered. * * * Upon authority, I consider this method of valuation correct. What the court should ascertain is the 'fair value of the property being used'; what complainant 'employs for the public convenience'; the 'present' as compared with 'original cost' (Smyth *vs.* Ames, 169 U. S., at page 547 * * *); and it is also the 'value of the property at the time it is being used' (San Diego Land Co. *vs.* National City, 174 U. S., at page 757 * * *, and see also Stanislaus Co. *vs.* San Joaquin Co., 192 U. S. 201 * * *). It is impossible to observe this continued use of the present tense in these decisions of the highest court without feeling that the actual or reproductive value at the time of inquiry is the first and most important figure to be ascertained."

In this decision value is used in two senses: one, value as the Committee has defined it; and two, as synonymous with cost.

In the Minnesota rate cases, it is stated that:

"The cost of reproduction method is of service in ascertaining the present value of the plant when it is reasonably applied, and when the cost of reproducing the property may be ascertained with a proper degree of certainty. But it does not justify the acceptance of results which depend upon mere conjecture."

This statement follows a discussion of the cost-of-reproduction method as applied to the determination of the value of a right of

way, which consisted largely of terminal property, in which it was held that the cost of reproduction did not give proper results.

This case sounds a note of warning against the use of irrational, or unsound, theories of reproduction, and the use of mere conjecture in making a reproduction estimate.

The Supreme Court has held consistently, in the older cases, that in determining value, original cost under original conditions, and reproduction cost under present conditions, were of the greatest importance, though other considerations, such as selling (market) price of the securities, worth of the service to the consumer, etc., were also of significance. In these older cases the Courts seem to have said that reproduction cost should be determined on the basis of present-day conditions, whether or not the corporation years ago had to take a series of steps involving expense which would not now have to be taken, or whether or not the property was built by piecemeal construction at a necessarily higher cost than would prevail if all built at one time; that "present-day conditions" means present-day prices, present-day methods, and present-day facilities for doing work, and that these should be applied under existing physical conditions.

With the original cost and reproduction figures in hand, determined as outlined above, and with such other information, historic and otherwise, as was available, the Courts have held that valuation should be summed up as a matter of judgment, giving due weight, not only to the results obtained by the application of these different measures, but incidentally to the degree to which the measures are equitably applicable.

The more recent and authoritative decisions of the higher Courts, though they still lean toward defining the cost of reproduction as the cost under present conditions, thus following precedent, also give strong support to the use of historic physical conditions, since, in determining the "fair value" of pipes originally laid in streets having no pavements, but in which pavements were subsequently laid at the expense of the city, they exclude from "fair value" the cost of taking up and replacing the pavements which would be included if one were to base "fair value" on the cost of reproduction under existing conditions. In other words, the sums allowed by the Courts in determining "fair value" are the sums which it would cost to lay the pipes under the physical conditions which existed at the time the pipes were laid. The subject seems to be in a developmental stage in the Courts.

In effect, the Courts in some instances appear to have recognized that a split standard, so to speak, or one which might be defined as reproduction cost under present-day material and labor prices, and historic or past physical conditions, in certain particulars, would do more substantial justice, or be more equitable in the results of its

application, than either the original-cost theory under historic or past conditions on the one hand, or the reproduction-cost theory under present conditions on the other. Under such a standard the owner enjoys the advance in general value standards indicated by the advance in cost of labor and materials, or suffers from the decrease thereof, if these have declined in value, and has recognition given to the conditions under which he made his investment.

May not the question fairly be raised: Has the conception of reproduction, based on present conditions, been a proper conception?

In the opinion of the Committee, this subject is of sufficient importance to justify full discussion of the question: What is the proper conception of cost of reproduction new? In this discussion the Committee will point out some of the difficulties to be met in formulating a rational conception of the problem, will then try to answer four questions, and finally draw its conclusion.

Difficulties to be Met in Formulating a Theory.—The original conception of reproduction undoubtedly grew out of simple conditions, such as would be met in estimating the cost of reproducing a building or a single structure. In this case, the difference between the original cost of the building or structure and the reproduction estimate would be due wholly to changes in prices of labor and materials and the change in methods of doing work. This simplicity of condition does not obtain in the case of a great property, the actual construction of which has extended over many years, many of the plant units of which have been renewed or replaced by larger ones than were originally installed, which has undergone changes and alterations, and the history and records of which have not been kept fully and completely. In such a case the making of a complete estimate of the cost of replacement or reproduction is a very involved undertaking.

When there are added the complexities due to the effect of works built by other companies than the one under investigation, or by municipalities, or to the growth of a community or rearrangement of transportation facilities of a community or section of country, elements are introduced, the proper treatment of which is vital to a reasonable estimate of the cost.

To obtain the reproduction cost of the property, shall it be assumed that all those things must be done that are or were necessary to create a new property in the same location as that of the existing one? It is usually assumed that all other existing properties or conditions affording facilities for, or offering difficulties to, the reconstruction of the property under consideration continue to exist as at present, in so far as they affect the cost of reconstruction; but one cannot forget that the property in question was not built in a day—nor during one construction period.

Nearly all the second, third, and fourth tracks, and side tracks, of steam railroads have actually been built years after the original construction, with certain disadvantages arising from maintaining traffic but with the advantages to be derived from the existence of a well-organized railroad over the entire route. The same thing is true of the construction of many existing structures, such as large buildings, bridges, signal and interlocking systems, and other more recent and modern adjuncts of the railroad systems of to-day.

The actual historic development of railroads has seldom been the springing to life of a new complete up-to-date property, but a growth over a long period of years, each company adding to its track and facilities as the needs of its territory and its business demanded. The same thing is true of water-works, gas, or electric properties, and other utilities in large cities. Under these conditions, it is clear that great care must be exercised in outlining the basis for estimates.

The four main questions to be asked and discussed are:

1.—Shall present or original physical conditions govern?
2.—Shall present or original prices govern?
3.—Shall identical or substitute plant be considered?
4.—What is meant by the word "new", as frequently used in connection with reproduction?

1.—Shall Present or Original Physical Conditions Govern?—A few examples of actual conditions encountered in connection with construction are presented.

Wachusett Reservoir.—This reservoir was built to supply water to the Metropolitan District of Massachusetts. To construct it, it was necessary to acquire land on which there were many buildings, and mills with their water powers. Included in the reservoir site there were also many highways and two railroads. As a substitute for the highways obliterated, others had to be built around the margin of the reservoir, and some were raised above the water level. One of the railroads was relocated for many miles at one side of the reservoir, and another was raised. To make the reservoir a better receptacle for water, the surface soil was stripped from its whole area. One main dam and two subsidiary dams were necessary for holding the water. Incidentally, under special laws, damages had to be paid for real estate which was not acquired, but which was said to be damaged indirectly by the construction of the reservoir.

Kensico Dam.—This dam, of the New York Water-Works, was necessarily located within the limits of an existing reservoir, the water of which could not be drawn down until two new temporary reservoirs had been created farther up stream to maintain the water supply. After these had been completed, the old Kensico Reservoir was drained and the old dam removed. After the completion of the

new Kensico Reservoir, the two temporary dams and reservoirs will be useless.

The AuSable Dams.—By building three dams on the AuSable River in Michigan, the Commonwealth Power Company flooded hundreds of acres to a depth of 40 ft. There was not a house, not a mile of road, no railroads, no damage to property of any kind such as was encountered in the other reservoirs. It was only necessary to acquire the needed lands and flowage and build the dams, without property damages in any appreciable amount.

There are now no buildings, roads, or railroads in the basins of any of these reservoirs, nor does the connection of the Kensico auxiliary reservoirs with the construction of the main dam appear. Therefore, in these three cases, presently existing conditions are not indicative of work done or difficulties encountered in actual construction in the past, nor of what it is fair to assume would be the conditions to be found had the reservoirs not been built. Conditions may be now essentially similar, immediately about these reservoir sites, but it would seem to be unfair for this reason to assume like conditions to govern the estimate of reproduction cost to be used as a basis of "fair value".

The theory of reproduction cost under existing conditions evidently was based on the reproduction of property units which now exist, such as, for instance, buildings, bridges, and other structures and works, and did not take into account that, in creating public service property, there may be much destruction as well as construction. The destroyed property obviously does not exist, and therefore would not be included in the inventory of property to be valued if the theory of determining the cost of property under existing conditions were followed strictly.

In addition to the destruction of physical property, cited in the foregoing, there may be the destruction of business and resulting damage to surrounding property, all of which may prove to be a large element of cost.

On account of the destruction of business, it became necessary in the case of the Wachusett Reservoir to pay for the resulting loss, not only to those owning the business, but to the workmen who were thrown out of employment, and to the owners of surrounding property not acquired for the reservoir but affected in value by the destruction of the manufacturing and other business in a well-populated valley. It is clear that such business will not exist at the time a reproduction cost is being ascertained, and therefore will not be an element of cost under existing conditions rigidly interpreted. The destruction of the business was properly an important element of cost in the creation of a reservoir at this site, would be reasonably certain to be an element of cost in the production of a reservoir at this site at any date of

estimate, if the existing reservoir had not been built, and therefore should be included as an element of cost of reproducing the reservoir.

Your Committee is of the opinion that all such items of cost, due to damages, destruction of property, purchase of rights, and temporary works, as cited in these illustrations, are clearly proper items to be included in the reproduction estimate when capable of historic proof. It would seem that, in such cases as these, fairness to the owners of the property and to the public would necessitate the use of historic conditions, at least to determine the extent, magnitude, and character of property units created, destroyed, or removed, physical evidence of which passed with the construction of the property itself, and which it may reasonably be assumed it would still be necessary to create, destroy, or remove were the property to be built new at the date of valuation.

Another series of examples may be found in the conditions which existed at the time of construction of certain great railway terminals.

The Pennsylvania Railroad Terminal, New York City.—This structure was pioneer construction. Land was purchased extending in a strip across the greatest city in the country. The property was built up solid with buildings, which were not only purchased, but wrecked, and the entire value thereof thrown away. There was no steam railroad traffic to maintain, but there was consequently no benefit to be derived from the existence of tracks for the removal of earth and construction débris.

The New York Central Terminal, New York City.—This terminal replaced an old structure, which in turn had succeeded others on the same site. The existing plant covers an extensive area, the larger portion of which was originally, with respect to the present undertaking, covered with buildings of all kinds and intersected with streets requiring treatment in various ways, as in the case of the Pennsylvania terminal, but in building this terminal, the company maintained a formerly created traffic without interruption, and though thereby the expense of construction was increased by the cost of temporary structures to provide facilities for its patrons, longer time of construction, and cost due to the hampering of operations by not having the entire site available for working purposes, it is probable that these elements of additional cost were largely offset by the savings that resulted from the utilization of the existing accessorial tracks for the handling of construction materials and the disposition of excavated materials in four-tracking the Hudson and Harlem Divisions.

Except with respect to the value of near-by lands, the present conditions about these two properties are much alike, and, for anything that appears, a reconstruction programme for one would be much like that for the other, under present surrounding conditions, and the offsetting effect of the revenue earned by the New York Central Railroad, against its increased cost due to maintenance of traffic, gives

color to the propriety of making like assumptions for both properties. But it should be remembered that only a part of the property of the New York Central Terminal had to be acquired in modern times. Much of it was acquired years ago, when it was not covered by valuable buildings, and it would seem to be unfair to assume, in a reproduction estimate which is to serve as a basis for "fair value", that all of it would be covered with valuable improvements, to be purchased and wrecked simply because surrounding land is now so covered, or because the property acquired by the Pennsylvania Company was so covered. Without the existence of the railroad, the City would not be the city that it is; it is what it is, partly as the result of the existence of the railroad, therefore it cannot be said that if the railroad had not been built, the surrounding lands, and presumably the site of the terminal, would be covered with the valuable improvements now in evidence. Here again it would seem to be fair to refer to history to determine what was done, and would reasonably be supposed still to be necessary to do, to construct the property new.

One illustration brought to the attention of the Committee is a case of a highway which originally crossed a steam railroad at a very acute angle, making a dangerous crossing to both railroad and public. At its own expense, the railroad acquired land parallel with its own, changed the course of the road for several hundred feet and made a right-angled crossing. It was argued that, "in case of reproduction, all other property remaining as at present", the highway would be in its new location and would not have to be reproduced. On this basis, many items which the owner of a railroad or other public utility was compelled to pay for might be cut out of an appraisal. But the highway would be in its original place were it not for the act of the railroad, and would have to be moved by any railroad, building presently, if the existing road had not been built; the evidence of the necessity, however, having been destroyed in the doing. The cost was a proper cost, capable of historic proof; and the Committee believes that it should be included as a cost in the estimate of reproduction.

A certain railroad was built through a heavily forested section of country, largely to develop the lumber industry in that section. The land was worth, and cost the railroad company, upwards of $40 an acre because of its timber value, and the company paid another $40 or $50 an acre, for clearing and grubbing. The timber industry developed, the surrounding lands were cleared and proved to be unattractive for agricultural development, and no large cities built up along the railroad. To-day the timber is gone, there is no clearing to do, and the land has depreciated to a value of $5 or $6 an acre. In this case human progress has taken away from the value of the territory, rather than, as is more usual, added to it. The railroad has

suffered as well, because its local business is largely gone. It has, however, as a part of a large property that has taken it over, developed a good through business. It would seem that all these things must be considered, when determining whether the original conditions for right of way and clearing, capable of proof, shall be used in an estimate of reproduction cost, or on the other hand what would be the present-day cost of acquiring the already cleared right of way. It is manifest that the railroad company contributed to the present condition, by providing the means for removing the lumber. Presumably its promoters should have been able to foresee what the general result of the lumbering operations would be, and should have reimbursed themselves, in the early days of the enterprise, for the possible future loss in value, due to the changed conditions, and in general it must be said that such enterprises assume the hazards of such results of human progress, particularly those to which they themselves contributed largely. Nevertheless this line, while apparently not now needed for the country through which it operates, and which, but for its connection with a greater property, would certainly have to be depreciated in value by at least the diminished cost of reproduction; yet, as a going property, adequately serving the public in its through business, it would seem to be unjust to take away from it all hope of future life as might result from a limitation of its return to "fair return" on a greatly depreciated actual investment.

One element of cost, being typical of a class and easily separable, deserves discussion by itself. This is the cost of removing and replacing paving of streets over and around public utility properties. It is of importance in connection with street railways and all underground conduit lines for gas, electricity, water, or other commodities.

Street railway properties occupying the streets of large cities do so under grants which vary widely in terms as to paving. In every case the burden is on the company to build such a type of construction as will permit that part of the public not depending on the railway company for transportation to enjoy the free and unrestricted use of the street.

A certain street railway company owns a large mileage of track in paved streets. In addition to the not uncommon case of tracks which were laid before the streets were paved, several different cases of complication as to paving are found:

Case 1.—The street railway company built all the track foundations, track superstructures, and pavement.

Case 2.—The street railway company built all the track foundations and superstructures, but the city built the pavement.

Case 3.—The street railway company built the track superstructure, but the city built the track foundations and pavement.

Case 4.—The street railway company built the track foundations and superstructure and took out and rebuilt existing pavements, but subsequently the city repaved the entire street at no expense to the company.

In making an appraisal of this property it will be necessary to define clearly what items shall be included in the reproduction estimate, and to answer, among others, these questions: Shall allowance be made for the removal of paving on all streets, whether they were unpaved or paved when the tracks were built? Shall allowance be made for all track foundations, or shall investigation be made as to what was done by the city, and that part excluded? Shall allowance be made for paving in all streets in which there is paving?

The Committee is of the opinion that in all cases where such questions are at issue, the terms of the contract should govern. The property built by the corporation under the terms of its charter or franchise, whether the items belong to the corporation or the public, is the property to be reproduced. Franchise or contract provisions usually settle all questions of ownership or of division of joint expense. Such provisions should govern as to the inclusion of all, or part, of the expense in the reproduction estimate. It is immaterial whether another corporation or the public is the other joint owner. The division should be made on a proper interpretation of contract or franchise, and in such cases as those cited, no expense to be borne by the city under the contract should be appraised to the railway company, and no expense to be borne by the railway company under the contract should be omitted in determining the reproduction cost. The position taken in some cases, that such an expense as paving is not a permissible capital charge and therefore not an item of cost of reproduction in the case of a street railway, does not seem to be tenable when the expense is borne by the railway company.

When a corporation is required, as is usual, to remove and replace paving when constructing works requiring such removal and replacement, there can be no doubt that the existence of pavement in a street makes the construction of tracks, or the laying of pipes or conduits, more costly than if the pavement were not there. When pavement exists, therefore, at the date of estimate, its effect on the cost of reproduction cannot be ignored, even though the extra cost should not be included when using the reproduction cost as an element of "fair value". The item when included should be scheduled separately, so that it can be omitted if that be the will of the determining body.

This subject has already been referred to under the caption "Title to Property Not Conclusive", on pages 1350 to 1353.

The item of clearing and grubbing railroad rights of way is one concerning which question has been raised. On few if any rail-

roads, is there any forest on the right of way. Along many miles of existing railroad there is to-day no evidence that there ever was any forest growth on the right of way, where history shows the existence of dense forests at the time of original construction. It is true that this is a minor question, because the rise in land values, if allowed, will in general—but not always—more than offset any possible loss to the company-owner by reason of the exclusion of the item of clearing and grubbing actually paid for, but no longer in evidence as ever having been necessary. The fact, that there may be offsetting advantages and disadvantages, does not affect the principle involved. The effort is to get a basis for the present-day value of the owners' investment. If, as a result of human progress, it would be reasonable to suppose that, at the date of valuation, the land occupied by the railroad would have been cleared, regardless of the existence of the railroad, and it is so cleared, it would seem to be fair to omit clearing from a reproduction estimate. If, on the other hand, it is fair to assume that, but for the presence of the railroad, the forest would still be there, the cost of clearing and grubbing should be allowed. There are cases in which one, or the other, of the assumptions herein made is clearly the correct assumption, there are other cases in which it is not so clear, as to whether the changed conditions are due to the railroad itself. Let it, as the party bearing hazards, be given the benefit of the doubt.

Another class of expenditures, that may be greatly affected by the choice of historic or present-day conditions, is that including promotion, organization, financing, interest during construction, and some other overhead charges, development expense, and the excess cost of piecemeal construction.

There will be no difficulty with respect to newly created properties. The question occurs with respect to old properties of magnitude, that have grown from relatively small beginnings.

In such cases most of these expenses would be relatively large for the original enterprise, and relatively small, or nothing at all, for the smaller additions as they have been made from time to time—although interest would always be an expense, and the others named would be incurred in greater or less degree on all but minor additions. And it may very well happen that important additions may be of such relative magnitude that all of this class of expenditures will be as large, in percentages of the property to which they apply, as were the original expenses of this class of the original property.

It would seem, therefore, that with respect to these items, the policy should prevail, of referring to the history of the property, to determine to what portion of the property, and how these items of expense, are properly applicable, just as has been advised for the determination of those items of physical property that are to be in-

cluded, not forgetting that at least the item of interest is applicable to the whole of the construction, but for varying lengths of time, and that development expense attaches to practically all additions of any considerable relative magnitude, and the excess cost of piecemeal construction to all minor additions.

Concerning facilities for doing work in general it would seem to be logical to use those of the period of valuation, but with respect to transportation agencies, this may work injustice in some cases. The Los Angeles Aqueduct, and certain other works, all built without near-by railroads to bring materials, men, and supplies to the site of the work, could now have the advantage of more recently constructed railroads. Have these great works, fully serving their several purposes, lost a considerable portion of their value by the development of transportation facilities not in existence when they were built? It would seem fair to say "no", even though this may seem to be inconsistent with the position taken with respect to most old properties. The uncertainties with respect to the details of facilities existing, or used in the construction of old properties, and the effect of these on unit prices, which, as will appear later, the Committee thinks should be as of the period of valuation for reproduction estimates, make it seem desirable and consistent to use present-day transportation facilities for most old properties, and historic facilities for some exceptional cases of old or recently constructed properties.

The conclusion of the Committee is that, while apparent present-day conditions, that would affect the cost of reproducing the property, must be considered in any logical estimate, yet history must also be considered to determine what is to be reproduced, the conditions under which it is to be reproduced, and how the estimates must be made; that for all those items, concerning which there can be no doubt, the engineer should use the basis plainly applying, and that for those that are doubtful, or have been questioned, he should present the effect of the use of the different bases clearly, that the determining body may have the data for a wise decision.

2.—Shall Present or Original Prices Govern?—Prices for labor and materials rise and fall, and the cost of doing work varies, as new machinery and appliances are invented.

The term "present prices" has sometimes been held to mean the prices of the day of estimate; sometimes the average prices of a greater or less period just preceding the day of estimate; and sometimes the prices of a similar period just following the day of estimate. By the term "present prices" the Committee means prices averaged over a period of time to produce what may be called normal prices, as is fully discussed under the caption, "Unit Prices".

One of the recognized bases of "value" of property is the sum that it would cost to produce that property or an exactly identical

property at the present time. Estimates of the "cost of reproduction" are made to show what the property could be produced for new at the time of appraisal, and therefore unit prices which were actually paid many years ago may not now apply. It would seem to be clear that, in estimating the cost of producing any property at a given time, unit prices which do not and cannot prevail at the time of the investigation should not be used; and, conversely, it would seem to be equally clear, without argument, that the prices for materials and labor should be those of the assumed time or period of construction.

Important decisions of the United States Supreme Court, on which the Committee bases its conclusion, that present prices for materials and labor should be used, are Willcox *vs.* Consolidated Gas Company and the Minnesota rate case. In the former, Mr. Justice Peckham says (212 U. S., 19, January 4th, 1909):

"And we concur with the court below in holding that the value of the property is to be determined as of the time when the inquiry is made regarding the rates. If the property which legally enters into the consideration of the question of rates has increased in value since it was acquired, the company is entitled to the benefit of such increase. This is at any rate the general rule."

The decision referred to is that of Judge Hough in Consolidated Gas Co. *vs.* City of New York (157 Fed., 849, December 20th, 1907).

"Upon authority, I consider this method of valuation correct. What the court should ascertain is the 'fair value of the property being used' (Smyth *v.* Ames, 169 U. S., at page 546, 18 Sup. Ct., at page 434 (42 L. ed. 819)); the 'present' as compared with 'original' cost; what complainant 'employs for the public convenience' (169 U. S., at page 547, 18 Sup. Ct., at page 434 (42 L. ed. 819)); and it is also the 'value of the property at the time it is being used' (San Diego Land Co. *v.* National City, 174 U. S., at page 757, 10 Sup. Ct., at page 811 (43 L. ed, 115)). And see, also, Stanislaus Co. *v.* San Joaquin Co., 192 U. S., 201, 24 Sup. Ct., 241, 48 L. ed., 406. It is impossible to observe this continued use of the present tense in these decisions of the higher court without feeling that the actual or reproductive value at the time of inquiry is the first and most important figure to be ascertained, and these views are amplified by San Diego Land Co. *v.* Jasper (C. C.), 110 Fed., at page 714, and Cotting *v.* Kansas City Stock Yards (C. C.), 82 Fed., at page 854, where the subject is more fully discussed. Upon reason, it seems clear that in solving this equation the plus and minus quantities should be equally considered, the appreciation and depreciation treated alike. * * * The so-called 'money value' of real or personal property is but a conveniently short method of expressing present potential usefulness, and 'investment' becomes meaningless if construed to mean what the thing invested in cost generations ago. Property, whether real or personal, is only valuable when useful. Its usefulness commonly depends on the business purposes to which it is or may be applied. Such business is a living thing.

and may flourish or wither, appreciate or depreciate; but, whatever happens, its present usefulness, expressed in financial terms, must be its value."

"As applied to a private merchant or manufacturer, the foregoing would seem elementary; but some difference is alleged to exist where the manufacturer transacts his business only by governmental license—whether called a franchise or by another name. Such license, however, cannot change an economic law, unless a different rule be prescribed by the terms of the license, which is sometimes done. No such unusual condition exists here, and, in the absence thereof, it is not to be inferred that any American government intended, when granting a franchise, not only to regulate the business transacted thereunder, and reasonably to limit the profits thereof, but to prevent the valuation of purely private property in the ordinary economic manner, and the property now under consideration is as much the private property of this complainant as are the belongings of any private citizen. Nor can it be inferred that such government intended to deny the application of economic laws to valuation of increments earned or unearned, while insisting upon the usual results thereof in the case of equally unearned, and possibly unmerited, depreciation."

"I think the method of valuation applied by the report to land, plant, mains, services, and meters lawful."

In the Minnesota rate cases, Mr. Justice Hughes says (230 U. S., 352, June 9th, 1913):

"It is clear that in ascertaining the present value we are not limited to the consideration of the amount of the actual investment. If that has been reckless or improvident, losses may be sustained which the community does not underwrite. As the company may not be protected in its actual investment, if the value of its property be plainly less, so the making of a just return for the use of the property involves the recognition of its fair value if it be more than its cost. The property is held in private ownership and it is that property, and not the original cost of it, of which the owner may not be deprived without due process of law."

The Committee believes that the foregoing decisions require the use of present rather than original prices in estimating reproduction cost. It recognizes, however, that undesirable fluctuations in the estimated value of property valued at intervals would occur owing to changes in prices. It suggests that this may be avoided and the value from year to year of a property which has been once properly valued may be determined if proper methods of accounting are adopted.

In the case of a new or recently created property, which has had from the beginning, under continuous and proper regulation, a modern system of accounting, which has taken account of all proper capital charges and credits, so that the amount of invested capital would be known at all times, such invested capital would be entitled to greater weight on equitable grounds as an indication of the so-called "fair

value" than an estimate of cost of reproduction less depreciation which might involve radical changes of prices; but we are not now discussing original cost to date, nor what is the proper basis for "fair value". For reproduction cost the Committee recommends that, in estimating, the prices prevailing at the assumed time of reproduction shall be used, meaning the normal prices obtained by averaging prices for a proper period, as is fully discussed subsequently in this chapter under the caption, "Unit Prices".

3.—Shall Identical or Substitute Plant be Considered?—Occasionally an estimate has been made, not of what it would cost to reproduce the existing unit, but of what it would cost to produce some substitute unit which would perform the same function as the existing unit.

For example, in a valuation of an old railroad, it was found that all the bridge piers and abutments and retaining walls built in the early years of the property were of stone masonry which would cost to reproduce new from $12 to $16 per cu. yd., and that all work built during the last 10 years was of concrete costing from $7 to $11 per cu. yd. It was argued that the modern construction, built at less expense, fulfilled exactly the same functions, and that, if the property were actually to be reproduced, stone would not be thought of. Undoubtedly, the original construction was used because it was the best available, and, in the judgment of the engineer and directors, this was a proper expenditure.

In one other case an engineer was making an appraisal of a large electric plant furnishing lights to a large city and power to several hundred miles of railroad. The power plant as originally built had been outgrown, and a second plant had been built alongside with about equal capacity. Both plants were working to capacity during the peak load, and both plants were well maintained. It was argued that one modern, up-to-date plant could be built which would cost less than the reproduction cost of the two and perform the same function.

Other illustrations of properties, which have been expanded to meet the need of rapidly growing cities and which in their present form represent very much larger investments of capital than would be necessary were actual new construction to take place at the present time, are afforded by the water supplies of some American cities. One western State capital affords an excellent example. The first water supply was obtained by pumping from a near-by source. Later, a supply was secured some 20 miles distant, but, in order to make use of an infiltration gallery, the water was taken at a point elevated only slightly above the distributing reservoir in the city, so that the capacity of the pipe was small in proportion to its size, on account of the limited fall. Large filter beds were located at this place; still later, an intake was located farther up stream, which made available a greater fall to the reservoir in the city; another feature is a large

natural lake used as a reservoir, fed by a small stream, not very far from the pipe line between the main source and the city, but at a higher level; still later, a great reservoir with a dam more than 200 ft. high was built in the mountains, far above the main source of supply.

It probably cannot be said that the company did not use reasonable judgment in the laying of each of the pipes and the building of the reservoirs and filters referred to, but if one were to design an equally efficient plant at the present day the water could be taken from farther up stream, so as to have an adequate head; it could be brought quite near to the city in a masonry conduit which would cost much less for the same quantity of water than the existing pipes; the lake or reservoir could be utilized at this level as a storage reservoir connected with the main supply; a single filter plant at the proper elevation, much higher than the present one, could be located comparatively near the city as a substitute for several independent filter plants; and two pipes having the same aggregate capacity as all the existing pipes leading from this filter plant to the city would cost much less than the existing pipes because of the much greater available fall. To use the estimated cost of the substitute plant in this city in lieu of the estimated reproduction cost of the present property would ignore a large investment actually and properly made by the water company.

The cost of reproduction being always required for the establishment of some relation between the public and its servant, the service corporation, either with respect to rates for service, purchase price, capitalization, or taxation, it would seem that the company should be credited with what it has actually produced in good faith and with what seemed to be good judgment at the time the property was created.

In the cases cited, the cost of substitute plants or property units altogether different from those actually built would vary very much from the reproduction cost of the existing property, and although such a substitute property, much less costly than the existing plant, might furnish equal or better service, it is not reproduction of service, but of property, that is under consideration; and clearly the estimate should be of existing property created with public approval, rather than of a substituted property.

In the case of the valuation of obsolete units of property still in service, where the unit is of a type not on the market and not possible to reproduce in kind at the present time at reasonable cost, it may be desirable to use the cost of a modern unit capable of performing the same service, but this would appear to be the only exception, and would seem to apply only to individual units, such as machines, which are not capable of being estimated by ordinary standards used in reproduction.

Reproduction in kind deals with facts, with properties that have physical existence and can be measured, inspected, and in many cases

their actual cost determined. Production of a substitute would be based more largely on speculation; different engineers would undoubtedly differ in their views as to the location, design, and cost of the substitute plant, and an estimate based on such a plant would be more difficult to support than one based on an existing plant, by reason of conflicting expert opinion as to the proper procedure.

Although the cost and efficiency of the substitute plant may have some bearing on the value of the existing plant, remote though it may be, it has none on reproduction cost of the existing property.

These views are in accord with the general practice of engineers who have engaged in appraisal work. These engineers have valued the identical property, and this method of valuation, when brought before the various Courts, including the Supreme Court of the United States, has met with approval, although the relative merits of the two methods have not been discussed by the Supreme Court. The principle that the identical property should be valued has been accepted apparently without discussion.

In the case of the Consolidated Gas Co. *vs.* City of New York, Judge Hough says:

"In every instance, however, the value assigned in the report is what it would cost presently to reproduce each item of property in its present condition and capable of giving service neither better nor worse that it now does. * * * Upon authority, I consider this method of valuation correct."

In the case of the Kennebec Water District *vs.* City of Waterville, Judge Savage says (at page 19):

"We think the inquiry along the line of reproduction should, however, be limited to the replacing of the present system by one substantially like it. To enter upon a comparison of the merits of different systems—to compare this one with more modern systems—would be to open a wide door to speculative inquiry, and lead to discussions not germane to the subject. It is this system that is to be appraised, in its present condition and with its present efficiency."

In harmony with the foregoing arguments, it is recommended that, for whatever purpose in connection with the relations of the public and the service corporation the cost of reproduction is required or desired, the estimate should be made with respect to the identical property, and not with respect to some substitute property to perform the same service.

4.—What is Meant by the Word "New", in the Phrase "Cost of Reproduction New"?—The words "Cost of Reproduction New" are of such frequent occurrence in valuation cases, and seem to have given rise to such diverse views, that, before the proper conception can be finally determined, it is necessary to give consideration to the proper weight to attach to the word "New".

For example, a certain logging railroad is 51 miles long. It was laid entirely with relayer rails; ten second-hand locomotives and certain second-hand cars were purchased and have been used for some years. It would be permissible under some conceptions of reproduction to estimate all this rail and equipment as new, but, such a conception would not appear to be proper. The term "new" in a case of this kind would apply to the character and condition of the second-hand materials as they were originally installed, and their depreciation would be measured by the difference between their condition at that time and at the date of valuation. The rail and the equipment are larger and more expensive than the road would be justified in buying if it bought them new. The property as "reproduced", if conceived to be new rail and equipment, is not identical with the original property when it was "new" or first built. There are costs estimated which did not enter into the original investment.

Another example.—On a little draw-bridge a motor has been installed which is in fact an old street railway motor capable of performing its new function indefinitely. It is of much greater capacity than would be needed for the bridge, and if a new motor had been installed a much smaller and less expensive type would have been selected.

In the examples cited it would seem that the properties when created "new" were partly second-hand, and the reproduction estimate should include relayer rails at relayer prices, second-hand equipment and second-hand motor at prices fair for the actual items at second-hand.

The Federal Valuation Act particularly requires that there shall be found: "The original cost to date; the cost of reproduction new; the cost of reproduction less depreciation."

In view of the wording of the Valuation Act, some have assumed that the word "new" requires the assumption of new rail in making a valuation, but that where records show that the material in the road was originally second-hand material, and is at present second-hand material, an initial depreciation equivalent in amount to the difference between the cost per ton of new rail and the cost per ton of relayer rail, such as was used, may be entered under the depreciation column. A further examination of the property itself at date of valuation will determine whether or not there is any additional depreciation, and to what extent it exists.

We speak of a new property and thereby refer to a property which has been created where no such property existed before. It may be of new material in all its parts, or it may be "new" as to grading, ownership of land, and many other of its elements, but have second-hand material and equipment entering largely into its construction.

If substitute units are to be excluded from consideration, consist-

ency demands that original conditions of existing units in their present service must be restored, and that no interpretation of the word "new" is to be permitted which places a property unit in any better or worse condition that it was in when first installed in present service. The property to be reproduced is the existing property. Each unit of property which is in existence is to be reproduced in the same condition as it was when it was put to its present service.

Conclusion as to the Proper Conception of Reproduction.—In line with the foregoing discussion, the Committee recommends that reproduction estimates be based on the assumption that the identical property is to be reproduced, rather than a substitute property; that while apparent present-day conditions, that would affect the cost of reproducing the property, must be considered in any logical estimate, yet history must also be considered, to determine what is to be reproduced, the conditions under which it is to be reproduced, and how the estimates must be made; that for all those items, concerning which there can be no doubt, the engineer should use the basis plainly applying, and that for those that are doubtful, or have been questioned, he should present the effect of the use of the different bases clearly, that the determining body may have the data for a wise decision; and that normal present conditions shall determine the prices and methods for doing the work.

WORK PRELIMINARY TO THE MAKING OF THE ESTIMATE OF REPRODUCTION.

The Schedule.—The first step in estimating the reproduction cost of a property is such a study of the property and its history as will enable the estimator to make a complete list of all items, lay out a proper financial and construction programme, and fix proper unit prices to the several items of the schedule.

Every appraisal offers its own problems, and it would be impossible for the Committee to lay down any fixed rules for the detail of appraisal that would be of universal or even of general application.

When the records of a company owner—maps, plans, specifications, deeds, and other titles to property—engineering records of construction and accounting records are sufficiently complete, it may be possible and permissible to make up schedules from the records and depend on inspection in the field to furnish a check on the records and to apply information to make good any deficiencies. Where, however, as is often the case, the records are incomplete and fragmentary, it becomes necessary to make most careful field schedules of the property, using the records as far as practicable to check field measurements and to furnish as much light as possible on the history of the construction.

Classification of Property.—For scheduling, the property should be divided into groups of items or units, preferably following some well-

established classification of accounts. For example, in railroad valuation, the grouping of items in each schedule should follow the grouping in the corresponding account of the Interstate Commerce Commission's Classification of Property chargeable to capital accounts. Where units of property or items of cost appear to have no place in such classification of accounts, but are clearly part of the cost of the property or are claimed as such, they should be set up as a sub-group, in the account that appears to be most appropriate.

Field Schedules.—When it becomes necessary to make surveys or field inspections in order to prepare the schedules, it is desirable that each property unit in each schedule be described so fully, and identified by such complete measurements, that no question could be raised as to its identification or as to the propriety of the use of the unit price that is subsequently assigned to it. It is entirely possible to prepare, based on field work alone, complete schedules of all visible physical property of a company operating any sort of a public utility, but it must be borne in mind that such schedules are not complete, because they ignore the history of the construction, and that by no means all the legitimate cost of creating or reproducing any property is represented by visible physical property, even where every item is capable of being fully measured. Careful consideration must be given to such history as shows any specially favorable or unfavorable conditions that may have been encountered during the construction of these items.

It must be emphasized that all items of material or work which entered into or were incidental to actual existing units are to be considered in the reproduced units as far as they can be determined.

Use of Records.—Most careful study of all existing records constitutes an essential part of the work of a reproduction estimate. Every plan, note, or cost record existing which relates to a plant unit measured and described in the field should be studied so that error may be eliminated and full data secured. It frequently occurs that plans are made for a structure and that during construction changes were made without notation on the original plans, such changes being indicated by fragmentary supplementary plans which are not preserved, or by no plans at all. In all such cases the appraisal record should correct the existing record as completely as practicable. Existing records should be used to the fullest extent to identify invisible items of property, such as underground construction or other inaccessible property, and to establish the nature and condition of existing items when originally installed.

Additional Information Not in Official Records.—Occasionally a case will be encountered where the history of the property is not to be determined with any degree of completeness from existing records, but on inquiry among former officials, former employees, consulting engi-

neers, contractors, or others who may have had connection with the property during all or a part of the building period, a large amount of thoroughly reliable information may be had which will throw great light on history and on costs. The use of all such data is highly desirable.

Little dependence should be placed on mere gossip or recollection unaided in any way by record, especially if it involves any increase in cost beyond a normal figure.

An illustration of the advantages to be gained from such an inquiry occurred in a recent valuation on a mid-western interurban railway. One of the branches of this road had been built as an independent line which changed owners once before coming into the hands of the present company. Aside from maps, a top-of-rail profile, and general data as to structures, all of which had been secured by a recent survey, the company had no records, not a word as to history, and nothing as to original cost. Inquiry developed the fact that all the construction records had been stored in the office of one of the officials, had not been turned over to the second owner, and after the death of this former official had been sold for old paper. Further inquiry yielded the names of one or two contractors. One of these men was visited. He went through his vault and unearthed complete profiles, copies of all progress and final estimates for grading, bridging, and track laying, plans for several bridges, and a large volume of construction photographs. With his aid, the men who purchased the right of way were found, and by their correspondence and receipts the original cost of most of the right of way (none of which was disclosed by deeds) was secured. This search disclosed the fact that many expenses were incurred which would not be even surmised by an examination of the property.

It is clearly the duty of the men engaged on an appraisal to take every precaution to secure to the fullest extent all data bearing on the actual work of construction as, in making an estimate of the cost of reproduction, due weight must be given to all evidence showing what the actual construction of the property included.

No Specific Assumptions as to Difficulties Where Not Capable of Proof.—In cases where no records are obtainable which will supplement actual field measurements and observed conditions, it would appear that the only proper course is to base the estimate of cost of reproduction on each unit of property as measured, assuming it to have been built under conditions which may be presumed from recent surroundings. To assume that the unit in question would cost less or more than the average unit, or that work has been omitted, or extra work done, in the case of a specific unit, when there are no records or obtainable data and nothing in the general property to justify the assumption, would be conjectural and carry little weight.

The Field Inspection.—The Committee deems it to be no part of its duty to undertake to outline methods in detail. It is proper to emphasize the necessity of full and complete records of field inspection in such form that they may be readily used in computation and fully indexed for filing. There is always a possibility of doubt regarding plans and records of old properties, uncertainty as to changes or abandonment, and, unless supported by field work, many really valuable records may be minimized in importance. It must be borne in mind that valuation work, especially the making of schedules, is of permanent value as a record of property, and that its value as a record for the Courts depends on the completeness of the description and identification of each property unit.

Many uncertainties can be cleared up, and much of the speculative character of estimating past conditions can be eliminated by good field work. There is a lack of significance, a failure to meet the requirements of appraiser or Court in every case where field inspection is hastily or carelessly made or no adequate record is made of the work.

Forms for Field and Office Record.—The use of forms is becoming so general and their value in securing uniform information from different field men is so great that there seems to be no ground for questioning their desirability or the propriety of their use. There are so many different forms required on a large appraisal and so many have been devised in connection with appraisal work in progress in the United States that no attempt is made to discuss the subject or to make suggestions. The adoption of full, complete, and carefully drawn field and office forms for field notes, schedules, and inventories is approved practice. The more completely all pertinent data regarding any class of property can be developed on a single set of forms without transcribing, the more satisfactory and convincing is the record.

Unit Prices on Physical Property Other Than Land.

There is no more important consideration in connection with valuation work than the correct determination of unit prices.

Necessarily, every large valuation involves a special study of the conditions which affect cost of work in the community and on the property, and of actual costs of various classes of work on the property under investigation. The prevailing rate of wages for different classes of labor, local prices on material, freight rates on material, or local contract prices, are by no means the only matters which are to be considered and taken into account.

Unit prices, or unit costs, which are finally determined upon and adopted as multipliers in the schedule should contain every element of cost which can be determined and allocated to each particular item.

A very erroneous result is likely to be secured if the appraiser adopts net cost for materials delivered to the property as shown by the vouchers for material, and actual contract figures for labor items, because in general these do not take into account all elements of cost to the owner.

In arriving at unit prices for final application, all relevant facts must be considered, and eventually sound judgment must be brought to bear on all data, if a proper unit is to be secured. The Committee desires to emphasize the fact that in the adoption of unit prices there is wide room for variation and error. A schedule may be made with the greatest of accuracy, field inspection may be most elaborate, and every possible check may be applied to the computations, but, if unit prices are carelessly adopted, which are too low or too high, a considerable error may be made easily in the valuation of tangible property.

The unit prices on most of the items entering into a valuation are not capable of exact and absolute determination or proof. This is especially true of all items in which labor largely enters into the cost.

The correctness of the figure finally adopted in every case depends in large measure on the reliability of records of actual costs, of similar units in recent years, the thoroughness of the study that has been made of those records, and the experience and soundness of judgment of the appraiser in the use of these studies and of other supporting data.

In the determination of unit prices the following general matters must be considered:

1.—What allowances should be made for contractor's profit in fixing prices?
2.—Shall unit prices be averaged over a period of time or shall actual prices as of the date of valuation be used?
3.—To what extent shall prices prevalent in piecemeal construction be considered?
4.—What should be included as elements of unit cost in fixing the price to be used?

1.—Contractor's Profit.—In assuming the reproduction of a property, the most reasonable assumption in general is that it would be let by contract, and that prices should be applied which would include the profit of contractors engaged on the work.

The fair total contract cost of the work, after award on fair competitive bidding, constitutes an equitable basis of unit cost determination, such cost including a reasonable profit to the contractor and necessary sub-contractors. To this should be added incidental unit

costs, overhead, administrative, and general costs incurred by the corporation, which are definitely assignable to the different units of property as part of the unit price.

There are cases, however, in which it would be a proper assumption that the company would establish its own organization, purchase its own plant and material, and do its own work.

The extent and character of the property under investigation, the actual history of the construction of the property itself, or the general practice in the part of the country in which it is located, will be the determining factors in arriving at the proper assumption to adopt.

When it is proper to assume that the company does the work itself, the estimated full cost to it should govern, including in the estimate proper recognition of the use of plant, hazards, and the fact that changes, modifications, and adaptation of the original plans generally occur and involve increased cost over the estimate, but no contractor's profit; unit prices should then be used, which represent what the estimated total unit cost to the company would be, by the method assumed to be proper.

2.—Shall Average Prices or Prices as of a Certain Date be Used? —When a valuation is made as of a certain date, it must be determined whether prices of materials and labor as of the date in question shall be used, or whether prices averaged over a period of years are more proper.

A study of the trend of prices of various commodities shows widely differing conditions. For example, Bessemer steel rail has remained steadily at $28 per ton, f. o. b. mills, since 1901 until recently; in some sections of the country lumber has increased with a fair degree of uniformity from 1901 to the present time, oak showing more than 50% increase, white pine more than 100% increase, and hemlock more than 50% increase; Portland cement, on the other hand, has decreased in some localities from $3 in 1880 to about $1 per bbl. in 1915, but increased in the year following; labor has steadily increased in recent years, with the upward trend still noticeable.

Other materials—an example of which is copper—have fluctuated, going up and down from extreme high to extreme low figures without any relation to changes in labor or other material prices. These facts compel most careful analyses of the records of the property under appraisal, and of other like properties in the same vicinity, to determine price tendencies, actual costs of work done, and special local conditions which affect costs, if average prices are to be used.

The illustration afforded by the Buffalo gas case (3 P. S. C., 2d Dist. N. Y., 1913), is given as showing the effect on valuation of price fluctuation. There were almost exactly 30 000 tons of cast-iron gas

pipe in question. The Commission summarizes the fluctuations as follows:

In 1897 when the property was taken over this would have been worth, at the prevailing price.	$547 500
Had a valuation been made in 1907, it would have been worth, at the price of that year.....	1 200 000
On the average prices of 5 years, 1893 to 1897....	617 700
On the average prices of 5 years, 1898 to 1902....	746 700
On the average prices of 5 years, 1903 to 1907....	944 400
On the average prices of 5 years, 1908 to 1912....	720 600

It seems to the Committee that what is desired is what may be termed normal present-day prices.

By normal, present-day prices is meant such prices, actual or average, as will be fairly representative of the period, but which do not reflect violent fluctuations up or down. These normal prices will be to some extent affected by changes in the market.

Many commodities, of which cement is an example, have had a downward trend, owing to increase in home manufacture and to improvements in the art. Other commodities, like lumber and timber of all kinds, have steadily increased in price owing to decreasing supply and greater demand. There can be no serious question as to the propriety of the use of normal, present prices, or prices averaged over 2 or 3 years at most, rather than the use of a long average which would bring the price above or below a proper, normal, present price.

In the case of such materials as iron pipe and copper, the price fluctuations of which have been violent during short periods, the problem becomes specially difficult. The actual construction of all large properties has extended over a period of years. An investigation of actual costs of construction on large properties will generally disclose the fact that materials have actually been bought at both high and low figures; frequently large quantities will be bought near one limit or the other. Actual cost, where ascertainable, gives actual investment in this material. Actual cost is not always capable of determination over the entire life of a property, and for such material as entered in during such period some arbitrary unit must be adopted, even in the case of "original cost" estimates.

The practice, adopted on some recent appraisals, of using a price derived from a weighted average of actual purchases over a period of from 5 to 10 years on the property under investigation, has the merit of using actual investment in recent years as a basis for determining a unit to be used on the entire property, and meets the objection raised by the Second District Commission of New York.

Present-day labor prices can be determined by an analysis of payrolls over such a length of time as will give proper actual averages

for each class of labor. By a comparison with similar data derived from records of other properties in the immediate vicinity, prices may be derived which are actual and are capable of proof. Prices thus determined would seem to be proper bases on which to build up estimates of total labor entering into the various units.

Any price which is used must be a matter of judgment, in the light of all available facts, but the arbitrary selection of a certain specific date as the date of appraisal does not seem to justify the use of prices which are abnormal. However derived, the prices used for fluctuating materials should be proper for the estimated period of reproduction which should end with the date as of which the investigation is made, and which should be sufficiently stable so that no reappraisal within a short time thereafter should make violent changes in estimates of reproduction cost.

3.—Piecemeal Construction.—Piecemeal construction has been defined to mean that kind of construction which is done piece by piece, and not at a single operation.

For example, the original pipe system of water-works and some important additions may be laid continuously in one construction period, either by forces of the company or by contract, but many additions must be made from time to time to meet the needs of an increasing population and a growing demand for water. These are necessarily short stretches of pipe, widely scattered, and are almost universally laid by the forces of the company at considerably higher costs than would prevail if the work could be done in connection with the building of an entire distribution system.

There are many kinds of construction, which always are built in what may be termed a piecemeal manner, which are not built at the time of original construction. Such work as the installing of water, electric, or telephone services, the building of industrial tracks and spur-tracks on the line of a railroad, the setting of meters and other forms of construction, is generally done in response to the demands of business development. Every effort of the management is bent to securing the greatest economy in doing this class of work; records are kept, and actual costs can be obtained over almost any period desired. Unit costs for this class of work can be determined from actual costs which are capable of very exact analysis and very definite proof by comparison with similar actual costs on other properties.

Whether or not unit costs should be determined on the basis of piecemeal construction, or on the basis of doing the work in a wholesale manner, depends upon the assumptions which are made with regard to the method of development of the property under which the estimate of reproduction cost is to be made. If on the basis of historic sequence, then the extra unit cost of piecemeal construction should be included; if on the basis of reproduction under present con-

ditions, during one construction period, then the extra unit cost of piecemeal construction should in general be excluded—the exceptions occur when it is assumed that the business is to be gradually developed in an assumed further period, in which cases it would be proper to use piecemeal unit prices for those items which would be so produced.

In the reproduction estimate, the property should be assumed as reproduced in the most economical manner and in reasonable sequence. Such assumption of necessity involves the building of some items of property that develop with the growth of business, not as part of the main property, but as following the main property, and at unit prices which would represent the actual cost of similar items of property built as they necessarily were or would be likely to be built by methods different from, and in some cases more expensive than, those that could be used on the main property.

4.—What Should be Included as Elements of Cost in the Unit Prices?—There has been an unfortunate lack of uniformity in valuation practice in the manner of arriving at the estimate of reproduction cost.

Apparently, some engineers have used material prices which were based on net costs at the point of delivery, and labor costs based on contract prices for performing certain work, and then, realizing that these do not give complete cost, but without making a full analysis, have added percentages to the total valuation for omissions, contingencies, incidentals, errors, contractors' profit, or other blanket items.

It may be that such a method, when used with good judgment, will lead to a result which is as close to the truth as when a more elaborate analysis is made, but it is much more difficult of satisfactory proof.

In the opinion of the Committee, the unit prices which are applied to specific items of property should include every element of cost to the owner capable of definite assignment to those items, and no such elements should be included as a blanket, overhead charge.

For example, the material may be purchased in the open market, the normal price may be capable of determination, and the freight rate to the point of use may be secured and applied, but to these two main elements there should be added, wherever they are properly applicable and obtainable:

(*a*)—The cost of purchasing;
(*b*)—House or material yard service;
(*c*)—Local transportation;
(*d*)—Waste, loss, and breakage;
(*e*)—Direct supervision.

(*a*)—*The Cost of Purchasing.*—The organization and expense of the purchasing department might with propriety be treated as an over-

head charge; it may with equal propriety be treated as a charge to material, and is capable of determination with definiteness in most cases. In the case of a large operating company, where purchases cover material for maintenance and also large expenditures for construction, there is grave danger of overlooking this item of expense. Usually an analysis of the accounts will give actual costs of purchasing of large quantities of material, thus permitting an allocation of purchasing costs on construction material.

(*b*)—*House Service or Material Yard Service.*—The cost of warehousing, material yard handling, or what may be termed "House Service" or "Material Yard Service", is an expense which on a large property is great in the aggregate although a comparatively small percentage on cost of material purchased. The extent of the charge and its division depends on how much of the material is purchased for direct delivery, how much goes through a material or storage yard, and how much goes into a warehouse for delivery in small lots as needed.

(*c*)—*Transportation.*—In almost all valuations, the greater part of the material involved incurs a transportation expense over and beyond the railroad freight rate to the point of delivery. In the case of railroad materials of all kinds, the material is usually purchased, f. o. b. cars, at the most convenient delivery point on the line of the road, and a haul of possibly several hundred miles on the company's own line is necessary. The determination of the average length of haul for the material of each class on a railroad and the determination of a proper rate to apply constitute a very important element in the determination of the correct unit prices. In connection with this matter of the rate, attention may be called to the fact that, under construction conditions, on a new road, with traffic all in one direction, without the advantage of an old established operating organization, the cost will exceed the cost of service on an old road. This has been recognized by the Oklahoma and California Commissions.

The local transportation may consist of haul by truck or wagon to the site, and, if so, is a present element to be computed, if not otherwise provided for. In estimating cost of transportation, it is to be assumed that all transportation facilities existing at the date of estimate—except the property under consideration in case it is a transportation property—are available.

(*d*)—*Waste, Loss and Breakage, or Overplus Over Measurements.*—These are elements of either unit cost or of allowance in measurement of quantities rather than of contingencies, for the reason that they vary so greatly, from nothing at all on some materials to a very considerable percentage on others. In this class would come allowances for sag in wire or cable, waste in lumber, loss and breakage in fragile materials, and all other allowances over net quantities which are necessary to in-

sure enough material to complete the work. In the case of some materials, quantities are derived by rules which give theoretical or geometric quantities, though the actual quantities moved and paid for may considerably overrun.

One very notable example of this is given in the Panama Canal Report for the year ended June 30th, 1912, which states that the geometrical quantity in the dredged channel of the Panama Canal, from deep water on the Atlantic side to a short distance beyond the shore line, was to that date 10 169 000 cu. yd., though the actual quantity taken out of the channel amounted to 22 886 000 cu. yd., an excess of 125 per cent. The great excess of dredging in this case over the geometrical quantity was due to the quantity of material washed into the channel by waves and currents.

There are certain standard weights of cast-iron water pipes, and pipes of these weights are ordered. As the pipe foundries cannot make pipes of the exact weight, the full price per ton is paid for any additional weight that there may be, up to a certain limit. The pipes are not allowed to run much below the standard, because it is provided that the thickness of the metal shall not be less than the prescribed thickness at any place by more than a very limited amount. The average actual weights, therefore, are more than the standard weights.

In valuing an earthen dam, the net volume in the embankment is generally measured or computed from the records, and it might be correct to use this net volume if the unit prices to be used were derived from the cost per cubic yard of other similar embankments. If, however, the unit prices to be used were derived from measurements of the quantity of material taken from borrow-pits for the purpose of building the dam, a considerable allowance should be made for the shrinkage of the material when placed in the embankment and consolidated, and for the waste of material which almost inevitably takes place in building a dam across a stream as the result of floods and other causes. The waste, as a rule, is exceptionally large when a dam is built by the hydraulic fill process.

It seems much better that judgment should be used in determining the actual quantities of material involved in a given construction than to make an allowance for such additional material as a contingency.

(*e*)—*Direct Supervision.—Inspection.*—It has been the custom in many appraisals to treat as an overhead charge, under the account "Engineering" all charges for Engineering, Inspection, and Supervision of work, and to base such charges on a general percentage of the entire physical property estimate.

The Committee holds the opinion that, wherever it is possible to do so, charges for direct supervision should attach to the different units or groups, rather than to the property as a whole, and that all

such charges as can be localized to certain materials, units, or groups should be treated as affecting the unit price, and should not be added as a percentage. This would permit the charge for general engineering to be treated as an "Overhead Charge" and include only those costs of general engineering, surveying, design, and supervision which were applicable to the property as a whole, and not capable of definite assignment to different groups of units or individual units of property.

As examples of elements of cost properly assignable to units or groups of units, the Committee cites the following cases:

The inspection cost on rail, water pipe, structural steel, and other materials purchased is capable of separation and inclusion in the unit price.

The local engineering and inspection costs of a large building, a dam, an underground conduit line, or other individual units or groups of units may be capable of analysis and comparison with like costs incurred in the construction of other like units, and a more accurate estimate is likely to be secured than if the total engineering charges be found as a percentage of the cost of the entire property, based on the experience with similar properties.

Each valuation must of necessity be an independent work, and each unit price should have such consideration as will insure that it is applicable to the case in hand, and that all elements, of which those above stated are only a part, have been taken into account. When unit prices for different items in the schedule are made up on the basis of the amount of labor involved, it must be remembered that the labor costs are by no means covered by the sums included for laborers on the pay-roll. There must be, in addition, proper allowances for insurance, injuries, and damages, lost time of monthly men, costs or losses due to interruption, or failure to co-ordinate the work at all times, decreases in efficiency due to such conditions, the cost of supervision, including accounting and timekeeping, and other actual costs.

When unit prices are based on contractor's prices, most of the items above mentioned would naturally be included by the contractor in such prices or as extra work, for which payment must be made to the contractor; but, wherever contract work is done, there is generally a considerable additional cost to the company as the result of subsequent work by its own forces.

Illustrations of Actual Cost Affecting the Cost per Unit.—One illustration which shows the extent of these items that have been referred to, and the desirability of more detailed analysis of costs than is frequently made, is that of an electric light and power property in the Middle West, in a city of more than 400 000 population.

During a period of 2½ years, the company spent in construction $9 476 000, divided as follows:

Actual material entering into permanent construction.		$6 808 000
Actual labor costs in building permanent work.....		1 515 000
Total cost of labor and material in structures capable of scheduling.....		$8 323 000
A.—Construction tools.....	$110 000	
B.—Store and supply expense.....	288 000	
C.—Purchasing expense.....	39 000	
D.—Injuries and damages.....	48 000	
E.—Engineering, general.....	122 000	
F.—Engineering, direct supervision.....	546 000	1 153 000
		$9 476 000

This does not take into account costs for interest, taxes, organization, or other costs which were incurred in the nature of actual overhead costs.

The aggregate cost, over and above those of bare labor and material, was 12.1% of the total, or 13.8% of the items capable of inventory.

It was found that full analysis of these costs gave very different percentages for different classes of construction, as for example:

Tool expense was approximately 2% of labor and material on overhead and underground construction, and 1% on buildings and equipment.

Stores and supplies expense, or the cost of handling, warehousing, and material yard, varied even more widely, as follows, being based on total material in each account:

Buildings	2.78%
Steam plant equipment.....	0.74%
Electric plant equipment.....	5.96%
Lines overhead and underground.....	7.35%
Other property.....	2.45%

Direct supervision, or those engineering and inspection charges which were capable of exact assignment, bore the following relation to total labor and material charges to each account:

Buildings	8.46%
Steam and electric plant equipment....	7.36%
Lines overhead and underground.....	4.60%
Other property.....	1.37%

These varying percentages are a strong argument in favor of more careful cost keeping on construction work and of more careful analysis

of existing records of actual cost, when a valuation of property is made.

Illustrations of Earthwork Unit Costs.—There are various classes of construction, such as earthwork, masonry, concrete, and other like construction, in which labor largely enters, where the conditions of construction may vary widely, and where there are available many contract prices, published or unpublished. The danger of basing a series of unit prices on contract prices, without analysis of further actual costs, may be shown by the discussion of one of these, and earthwork appears to offer a number of excellent examples.

In building a railroad or other property involving large quantities of earthwork, it is usual to pay for material, according to classification, as earth, loose rock, solid rock, etc. It is also usual to pay for overhaul beyond a certain specified haul limit.

In making estimates of cost of reproduction, unless all original notes, profiles, and estimates are available, it is a difficult and expensive matter to secure even a close approximation of actual yardage, and practically impossible to determine classification of loose rock, hardpan, or other material the character of which changes due to the effect of weather, or the identity of which may be concealed by growth of vegetation or otherwise. It is equally difficult to determine the quantity of overhaul or the amount of work which may have been done as a necessary incident to the grading of the embankment, such as changing of stream channels or roads.

All these things were encountered in the building of the property, and must in some way be accounted for in its reproduction. In some cases the unit price on unclassified earth in place is the fairest figure, and capable of better support than would be the attempt to classify or to separate overhaul.

In addition to these elements of cost which may be encountered in all earthwork, the railroad company encounters the expense to the company of transportation of men and contractor's plant, and the cost of work done after the contractor leaves the job.

The adopted unit price should be such a figure as will cover all expense, of every nature whatsoever, as is directly chargeable to grading the measurable embankment. Three or four examples will illustrate the possibility of grave error in failure to analyze unit costs sufficiently:

Example 1.—A high-class interurban railroad built in Michigan during 1912-13-14.—

Total material moved.....924 630 cu. yd.
Contract price of overhaul.....0.01 per yd. station.
Hardpan, if encountered, to be paid by agreement.

In this case the company actually paid on its final estimate for:

774 387	cu. yd.	earth	at $0.28	$216 828.36
1 860	" "	loose rock	" 0.40	744.00
300	" "	solid rock	" 1.00	300.00
776 547	Total classified material at prices named in the contract.....			$217 872.36
148 083	In addition to which, there was allowed: cu. yd. "Hardpan" and "Wet Earth" at 38, 40, and 50 cents.....			60 912.94
924 630	Total cu. yd., unclassified, at $0.30, average.			$278 785.30

It thus appears that the "rock" is a negligible item, but that the average cost of the unclassified material exceeded the contract price of earth by 2 cents per cubic yard.

In addition, the company paid:

For overhaul.....	$29 237.51
For force account on work after contractors left...	13 988.42
Total.....	$43 255.93

Thus making the total direct cost of the work $322 011.23, or an average of $0.348 per cu. yd.

Practically all of this excess was for elements of cost which could not be determined from either a careful reinspection of the property or from most accurate measurement, and, if reflected in the reproduction estimate at all, must appear in the unit price.

Example 2.—Among the exhibits introduced in the Minnesota rate case was one by A. H. Hogeland, M. Am. Soc. C. E., Chief Engineer, Great Northern Railway, entitled "Hogeland, 2d Amended Exhibit 4", which gives in detail the cost of grading on lines built between 1898 and 1910 aggregating 1 553.2 miles. This exhibit shows the contract prices for each class of material, and also the total charges to grading. The exhibit shows the details for each line built during those years.

A very brief abstract of this exhibit shows:

Earth...	28 693 523	cu. yd.	average contract price 19.3 cents	$5 545 074.31
Hardpan	9 260 156	" "	" " " 34.7 "	3 211 293.53
Loose rock..	3 115 093	" "	" " " 40.7 "	1 270 666.25
Solid rock..	6 209 349	" "	" " " 94.7 "	5 876 720.69
	47 278 121	" "	average of all..... 33.6 cents	$15 903 754.78

Brought forward		$15 903 754.78
It is to be noted that, over and above these contract prices, the company paid for overhaul, force account items, transportation, and other such charges, the total sum of		4 928 725.25
Total cost		$20 832 410.03
Average cost per cubic yard	44.11 cents	
Cost in excess of contract price	10.5 cents	

These figures are affected by the large yardage of rock, which presumably could be largely determined in a valuation. In order that rock be eliminated, an analysis of this exhibit was made and 300.29 miles having no rock were tabulated separately.

On this mileage the total yardage moved was 3 293 244 cu. yd.
Total contract price, $506 869, an average of 15.4 cents per cu. yd.
Total Company cost over contract, $264 727, or 8 cents per cu. yd.
A total cost of $771 596, or 23 cents per cu. yd.

It is here shown that actual cost per unit exceeded contract price per unit by 52.22 per cent.

Example 3.—A steam railroad built in Wisconsin in 1912 and 1913:

Total contract price for grading		$1 259 567.81
Extras		
Contractors extra bills	$42 830.86	
Railway Company labor	8 413.74	
Train service	215.03	
Rental of equipment	522.79	
Miscellaneous material and labor	2 028.98	
Transportation of contractors men	46 736.96	
Transportation of equipment	73 483.36	174 267.72

Percentage of extras to contract price 13.84 per cent.

In this contract there were the following quantities:

Earth excavation, 4 097 881 cu. yd. at 20 and 22 cents	$868 314.66
236 300 " " classified material	137 589.38
4 334 181 cu. yd., at average 23.2 cents	$1 005 904.04
Added to this was overhaul	253 663.77
	$1 259 567.81

Thus the overhaul added to the cost 6 cents per cu. yd., or 25 per cent.

"Example 4.—In the construction of the Musconetcong tunnel of the Lehigh Valley Railroad, the contract cost, based on unit prices,

a list of which is given in Drinker's 'Tunneling' (page 1085), was $883 938, whereas the actual final cost, including the payment of contractors' claims not settled until four years after the completion of the tunnel, was $1 282 149, an increase of nearly 50% over the cost as reflected in the commonly accepted unit prices."

These few examples indicate clearly the danger of adopting arbitrarily, as a unit price for reproduction cost, some figure based on a contract price or an average of contract prices, without most thorough study of the results of actual similar work. Many other illustrations as to the effect of the several elements of cost on the final price of various classes of work into which labor largely enters, and in which the hazards of construction are great, might be cited. Enough has been said, however, in the opinion of the Committee, to emphasize the statement that in each case conditions must be examined to find out what elements of cost do enter into the unit price, and that each unit price must be supported, if supported at all, by actual costs of similar work under similar conditions.

Unit costs found by general inquiry of supplying companies, engineers, contractors, and others are rarely reliable because of the lack of full knowledge on the part of those furnishing the information concerning the character of the work and the specifications and conditions under which it is to be done, and because of the fact that they are not likely to make the detailed, intelligent study which might justify subsequent expression of opinion. Even competitive bids on detailed specifications may not furnish reliable figures. Recent actual final construction costs on the plant being estimated or on similar properties, located under similar conditions, furnish the safest criteria. All such data should be interpreted in the light of sound judgment and wide construction experience.

An examination of the tabulated bids of any large contract letting will disclose the unreliability of individual opinion. It must be borne in mind that such bids are based on identical plans and specifications and conditions. It is not at all unusual to find variations in bids on individual items varying from 15 to 40% to as much as 100% or more. In some cases the opinions of contractors, as expressed by their bids, may represent a proper figure based on wide experience and full knowledge of local conditions, but other bids may be in no wise representative, and be radically high or low.

To conclude the discussion of unit prices, the Committee is of the opinion that a rational sequence of construction should be followed in the reproduction of a property; and that rational assumptions should be made as to the manner of doing the different parts of the work, whether by the forces of the company or by contract. Unit prices, based where possible on the actual cost of doing similar work, in a

similar manner, under similar circumstances, should be determined by persons of experience and sound judgment.

If, on the basis of the assumed conditions, piecemeal construction is required, and if the most appropriate way of executing such piecemeal construction is by doing the work directly by the company's forces within the assumed periods of construction and development, then the cost of work done in this way should be used in determining the reproduction cost. If the assumed conditions indicate that other portions of the work could be done more economically by contract, then the unit prices should have as their basis the price which a contractor would charge for doing such work, but to this must be added all other elements of cost or expense to the owner which can be separately allocated.

The unit prices should be based on the normal average cost of work for a considerable period—say, 5 or 10 years—in order to give stability to the valuation, so that it may be used for a subsequent term of years. In the case of items which are steadily increasing or decreasing in value, the prices adopted should be normal for the time of the valuation.

Full consideration should be given to the time allowed for construction, and due weight given to climatic conditions and the effect of weather on the cost of the work.

The Committee emphasizes the necessity for full information from trustworthy sources as to the actual complete cost of doing similar work under similar circumstances. The greater the amount of such data, making possible the adoption of complete and correct unit costs, the smaller the amount of overhead percentages which are necessary for providing for proper total construction costs.

The Cost of Reproducing Land Holdings.

For the reproduction cost of land holdings the Committee will base its arguments and conclusions on the law as expressed by selected and apparently authoritative Court decisions, and on those results of attempts of public or private purchasers to acquire properties for public purposes which are of common knowledge to engineers and others having to do with such matters. Examples of some of these results, fortifying the arguments and conclusions of the Committee, will be given.

Lands not All of Similar Character.—Classes of Land.—Not all lands acquired by public service corporations fall under one class; there are radical differences, and it is essential that a proper classification of them be made in any valuation.

Three classes result from a consideration of the extent and character of the acquisition:

1.—The acquisition of a single whole parcel, which may be selected from among several available parcels.

2.—The acquisition of a number of whole contiguous parcels to form a tract of moderate size.

3.—The acquisition of a number of parcels, both whole parcels and parts of parcels, to form a continuous strip, such as a railroad right of way, or a large body, like a collecting or storage reservoir.

1.—Single or Detached Parcels of Land.—In many instances lands are acquired and used by public service companies, which are in detached parcels of ordinary size, not connected with the other lands owned or used in the conduct of the business. These lands are not acquired in response to a need for the particular parcel. Any parcel of the same or similar area, in the same general locality, would meet the requirement of the company nearly or quite as well. Examples of this class are seen in lands acquired for electric generating- or sub-stations, car barns, warehouses or material yards, gas plants or gas-holders, office buildings, and other similar uses.

It may be that location on a water-front, or a point of convenient access to side-track facilities, is a desideratum, but any one of several parcels, which meets those requirements in the vicinity, may serve the purpose. It would seem to be clear that in such cases the same general laws which regulate values of land for any other purpose in the immediate neighborhood would govern, and that the reproduction cost of the land would be fixed by the value of other lands used for general purposes, as shown by sales, asking prices, or in any other manner that is usual and proper.

Presumably, the public service corporation, in the same way as an individual seeking a factory site or residence, would have a fairly wide range of selection and would choose that tract which would meet the requirements and could be had at the most reasonable price. It is fair to assume that such purchases would be at substantially the market value of lands in the vicinity at the time of acquisition, and would be subject to the same increase or decrease in value as other near-by similar lands the values of which would be affected by the same causes.

Therefore, it would appear that the reproduction cost of such a holding as an ordinary lot, or a tract of not unusual size, which is entirely disconnected from other holdings, should be based on adjacent or near-by land values for general purposes, should include no severance damages, but should include a reasonable allowance for the costs of acquisition.

2.—Tracts of Land.—Tracts of land of considerable area, including a number of lots or blocks, offer a more difficult case, for, aside from any such expenses as vacation of streets or alleys, or other work done to bring the tract as a whole into a usable condition, there is likely to have been originally an element of enhanced cost, due to the fact that the demand for a large number of contiguous small parcels tends to enhance the price rapidly, and even in a district where a large part of the lands are for sale, the demand affects the price before all can be acquired. Usually, in the acquisition of such a body of land, made up of many small parcels, some owners will have to be dealt with who are unwilling sellers and who hold out for an extreme price, making necessary either condemnation, or the forced payment of a higher consideration than would ordinarily be the case. Any condition necessitating the purchase of a number of adjacent parcels and uniting them into one large tract suitable for a specific purpose tends to remove the transaction from the simpler first case and take away the free choice of sites. Such cases demand a much more careful study of costs, especially with reference to recent accumulation of property of the same kind.

It may be seen readily, for example, that the purchase of 50 or 60 lots from numerous owners may increase the price per lot far above the normal price under a demand for only one lot or a few lots. The immediate demand for all the lots may and usually does add materially to the cost of the whole. Later, the demand being supplied and ceasing, prices drop to the old level, so that a valuation based on later sales of neighboring lots would show less than original cost and less than any possible cost of reproduction at the time of making the estimate.

Although general land values will have an important bearing on the price, consideration based on actual experience in comparable situations should be given to the effect of the large and pressing demand.

It is argued that, in such a case as the one cited, actual original cost, and not reproduction cost based on present land values, would be ample allowance, especially as in many cases the actual original cost of the assembled tract would be considerably in excess of the present value of neighboring lots for general purposes. It would seem to be fair, however, in those cases in which the original cost of an entire assembled tract exceeded the total market value of all the separate parcels at the time the acquisition was commenced, to assume that, if general values of lots increase in the vicinity, the cost of reproduction of the tract acquired for a specific purpose should, as a general rule, increase *pro rata.*

Similar questions are raised where lands are acquired for the extension of an existing plant. In such cases, prices may be and sometimes are demanded and necessarily paid which are far above normal.

In the cases cited there may be some freedom of choice as to the exact lands, but the difficulties due to acquisition of numerous parcels will be encountered no matter which of several possible tracts is selected. The reproduction estimate should be based on the value of land in the vicinity, the figure adopted including the incidental costs of acquisition of private titles, severance damages, if there was any severance, and the cost of acquiring any rights requisite for the use of the tract as a whole, such as vacation of streets or alleys, and the purchase of leases. All recorded excess costs above a normal market value should be given due weight. Only thus will the present reasonable cost of reproduction be obtained.

3.—Connected Strips or Bodies of Land.—By far the greatest difficulty arises when required lands constitute a connected strip or body, and there is no option in the choice of lands, all of which must be acquired to form the required strip or body.

An example of this class is furnished by a steam or electric railroad right of way. Here, the lands are a narrow strip, not purchased in ordinary commercial units of 10, 20, or 40-acre tracts, or of lots or other subdivisions of a plat, but in small fractions of such tracts taken without reference to the effect on the remainder of the tract from which they were taken. The location is determined by topography and continuity of route, and may not be varied on account of the objections of a land-owner. All the right of way must be acquired.

Another example is that of flowage lands for a reservoir. In this instance, many entire parcels must be acquired, and unless a greatly excessive acreage is taken, many irregular fractions must be bought. Here, as in the railroad right of way, conditions of topography and continuity govern. It must be this particular land and no other, and all of it must be had.

All valuations of lands acquired for any use where all must be had, and no choice or option as to the selection is left the purchaser, must rest on the same general principles of valuation. The Courts have clearly established the general principles which govern the fixing of value of property condemned for public use.

All elements of value must be considered. The owner must be recompensed, not only for the value of the land taken, but for all damages or losses of value suffered by him on account of the taking.

Under the law interpretation of just compensation, there can be no doubt that in cases of water-works reservoirs, railroad rights of way, flowage lands, or other properties of like nature, where the lands are not necessarily in uniform parcels, and where part of the land is taken and part cut off and left, just compensation will include the value of the lands taken and the money equivalent of any damages suffered by the owner by reason of the taking. This is all value to the seller and represents what is taken from him.

It would seem that these same principles are applicable in the valuation of such property in making a reproduction estimate.

The Term "Just Compensation" as Defined by the Courts.—The Constitution prescribes that private property shall not be taken without just compensation. The rules governing the condemnation of private property have been thoroughly established by a long line of decisions. All elements of value must be considered. The owner must be recompensed, not only for the value of the land taken, but for all damages or losses of value suffered by him on account of the taking.

The terms, "compensation", "just compensation", "due compensation", etc., have been defined in many cases.

In Virginia & Truckee R. R. Co. *vs.* Henry, the Court said (8 Nev., 165):

"It is difficult to imagine an unjust compensation; but the word 'just' is used evidently to intensify the meaning of the word 'compensation'; to convey the idea that the equivalent to be rendered for property taken shall be real, substantial, full, ample; and no legislature can diminish by one jot the rotund expression of the constitution. So are all the decided cases. While courts have differed upon minor points, two of which the statute of this state settles, namely, the allowance for particular benefit derived from the construction of the railroad and the exclusion from the calculation of damages of the cost of necessary cattle guards and fences when the petitioner offers to construct, yet upon the great substantial underlying basis upon which only can arise a constitutional law for the taking of private property for public use—the absolute protection of the individual by just compensation—there has been, could be, no dispute."

In Pick *v.* Rubicon Hydraulic Co. (27 Wis., 445), the Court said:

"In the case of Bigelow *vs.* The Western Wisconsin Railway Co., decided by this court at the present term, it was held that 'just compensation' consists in making the owner good, by an equivalent in money, for the loss he sustains in the value of his property by being deprived of a portion of it; and that it includes not only the value of the portion taken, but also the dimunition in value of that from which it is severed. In establishing this rule, we followed the reasoning of this court in Robbins *v.* Milwaukee and Horican R. Co., 6 Wis., 636; in Snyder *vs.* Western Union R. Co., 25 Wis., 60; and in Welch *v.* Milwaukee and St. Paul R. Co., 27 Wis., 108; and adopted the doctrine of numerous adjudications by the courts of other states upon the same subject."

The cases cited show the general rule as to the taking of lands by condemnation. There can be no doubt that, in the case of a waterworks reservoir, a railroad, flowage lands, or other property of like nature, where the lands are not necessarily in uniform parcels, and where part of the land is taken and part cut off and left, any amount necessarily paid as just compensation or as damages is a cost which

cannot be evaded by the purchaser. It is value to the seller, reimbursing him for what has been taken from him. It is an actual cost to the purchaser which is properly chargeable to the capital account.

The reproduction cost, or present cost of acquisition, does not include elements of value arising subsequently to and because of the taking for utility purposes. It includes only such sums, for the land itself, as the several owners would be entitled to in case of present acquisition, plus costs of purchasing.

Same Elements Must be Considered in Valuation as in Fixing "Just Compensation."—It would seem to be clear from a study of all the cases that, in valuation of lands which partake of the nature of rights of way or flowage lands, the same principles should govern as in condemnation, and all such elements should be considered in valuation as are taken into account in fixing just compensation in condemnation. Thus, the cost to the utility at the time of acquisition is not to be substituted for, or taken to be, the equivalent of reproduction cost, because the land may have declined or increased in value since the acquisition. Nor does the source of the title, or of the funds used to acquire, affect the matter, because that which is paid for out of surplus, or that which is donated, is as much the property of the company owner as that acquired by the expenditure of other capital and payment of full value.

The market value of the land actually taken from an owner is one element of cost, the damage to remaining and adjacent lands of the same owner is another, the costs of all investigations of title, attorneys' or agents' fees, surveys, plans, and expenses, and all other costs in connection with the transaction, constitute another. All taken together make up the price of the property acquired, and, as a general rule, in the absence of mistakes, dishonesty, or extravagance, may be taken as the value at the time of investigation. As said in the Minnesota rate cases (page 451):

"It [the utility] would be free to stand upon its legal rights and it cannot be supposed that they would be disregarded."

Thus, the presumption is that the amounts in condemnation judgments are not excessive. And, as a general rule, in the case of acquisition by purchase, it may be assumed that the utility does not pay more than the owner is legally entitled to receive.

All these elements of value for which "just compensation" would be rendered in a condemnation, exist in greater or less degree and must be considered, whether the land was actually acquired by condemnation or by private purchase. It occasionally happens in the case of many corporations not having the right of eminent domain, such as hydro-electric power properties in some States, that the prices paid are excessive of necessity.

Market Value of Adjacent Lands, per Acre, Not Always Conclusive.—It must be remembered that general land values are based on sales where a willing seller deals with a willing buyer. In the case of farm lands, for example, a man who desires a farm in a certain locality has the choice between a number of pieces that are on the market. He may be satisfied with one 40-acre farm, but considers the price too high. He has the option of paying the price or taking another farm at a lower price. As has been said, the railroad or the water company has no such option, but must take that parcel and no other. Experience has shown that condemnation juries often fix a high price and that often it is better business judgment to pay as large a sum as the condemnation prices, in order to avoid the expenses of condemnation, the delay caused by the proceeding, and the feeling aroused in a community by litigation. It often occurs that contiguous lands have not the same availability or value as the lands acquired by a utility, and only when they are comparable can the market value of such lands be used as a basis for estimate.

From the nature of the strips of land acquired for public utilities, the compensation paid, when measured in terms of dollars per acre on lands actually taken, appears to be very high compared with the per acre price paid in sales of similar lands for general purposes.

For example, a railroad company condemned a strip of land, 100 ft. wide, across a tract containing approximately 40 acres, cutting it in two nearly in the middle. The strip taken was 1 600 ft. long and contained 3.65 acres, leaving 36.25 acres to the owner, divided approximately 20 acres on one side of the road and 16 on the other. The building of the railroad necessitated changing fields and drainage, introduced two farm crossings with gates to open and shut in perpetuity, and not only cut off a corner of an orchard, but introduced a fire hazard, as the stables were near the line.

All these considerations caused a jury to fix as compensation the sum of $100 per acre for land taken, which was a fair figure based on several recent sales, and the further allowance of $15 per acre as the damages to the remainder. The compensation, therefore, was, for land, $365, for damages, $545, a total of $910, to which was added acquisition and overhead costs in excess of $170, or a total cost to the company, exclusive of interest, of $1 080, or almost exactly three times the acreage price fixed by the jury.

Several purchases at private sale in the same county were at approximately the same figure.

In some of the early valuations, notably the State railroad valuations in Michigan, Wisconsin, and Minnesota, the attempt was made to establish the relation between sales to railroads and sales to individuals by a study of the record of actual sales. Based on these

studies, a system for fixing the cost of reproduction of railroad lands by the use of multiples applied to farm land values was adopted.*

The Michigan tax cases, in which this method of valuation was used, reached the Courts without any contention being raised as to the methods or results of the valuation, but on other issues. Hence, the question was not passed on. The Minnesota valuation of land by this method became an issue in the Minnesota rate cases, and the method was not approved by the Supreme Court.

The Minnesota Rate Case Decision.—In many respects the most important decision bearing on land valuation is that of Mr. Justice Hughes in the Minnesota rate cases. This decision is of such importance, and has had so many interpretations placed on it, that extended quotation from it appears to be desirable. The decision must be construed as a whole, and all parts of it bearing on the subject of land must be studied together, in arriving at a conclusion as to the exact meaning. (Simpson *et al.*, constituting the Railroad and Warehouse Commission of the State of Minnesota *v.* Shepard, 230 U. S., 352, *et seq.* (1912), Syllabus, page 355.)

"For fixing rates the basis of calculation of value is the fair value of the property of the carrier used for the convenience of the public." (Smyth *v.* Ames, 169 U. S., 466.)

"There is no formula for the ascertainment of the fair value of property used for convenience of the public, but there must be a reasonable judgment having its basis in a proper consideration of all relevant facts. * * *

"Assets and property of a carrier not used in the transportation business cannot be included in the valuation as a basis for rate-making.

"Property of a railroad company cannot be valued for a basis of rate-making at a price above other similar property solely by reason of the fact that it is used as a railroad, and increases in value over cost cannot be allowed beyond the normal increase of other similar property."

After setting forth the values allowed by the Master and the Court below for land in the Northern Pacific case, stating the contentions in the case, and quoting from Mr. Cooper's testimony at some length, in order to show how he arrived at his estimates of value, and after bringing out the fact that "market value", as used by Mr. Cooper, was intended to mean, not the value of land for general purposes, but what it would cost the railroad to acquire the land, the Court says:

1.† "In reviewing the findings, the court below reached the conclusion that 'the master in effect found that the cost of reproduction

* "The Valuation of Public Service Corporation Property", by Henry E. Riggs, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXII, pp. 59–64, inclusive. Discussion by the late W. D. Taylor, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LII, p. 359. Report of Mr. Dwight C. Morgan to Minnesota Railroad and Warehouse Commission.

† Paragraphs are numbered by the Committee for convenience in referring to them in discussion.

and the present value of the lands for the terminals in the three great cities, including therein all cost of acquisition, consequential damages, and value for railroad use which he allowed, was only about 30 per cent. more than the normal value of the lands in sales between private parties. He found the value of the lands outside the terminals to be only twice their normal value.'

2. "From our examination of the evidence we are unable to conclude that the excess stated may be thus limited. What is termed the normal value does not satisfactorily appear. It further will be observed —from the summary of valuations we have set forth in the margin— that the amount thus allowed in item 1 for lands, yards, and terminals, both in and out of the three cities ($21,024,562), was included in the total on which 4½ per cent. was allowed in item 30 for 'engineering, superintendence, legal expenses', and again was included in the total on which 5 per cent. was allowed in item 37 for 'contingencies', and, in addition, was included in the total on which 10 per cent. was allowed in item 39 for 'interest during construction'.

3. "These are the results of the endeavor to apply the cost-of-reproduction method in determining the value of the right of way. It is at once apparent that, so far as the estimate rests upon a supposed compulsory feature of the acquisition, it cannot be sustained. It is said that the company would be compelled to pay more than what is the normal market value of property in transactions between private parties; that it would lack the freedom they enjoy, and, in view of its needs, it would have to give a higher price. It is also said that this price would be in excess of the present market value of contiguous or similarly situated property. It might well be asked, who shall describe the conditions that would exist, or the exigencies of the hypothetical owners of the property, on the assumption that the railroad were removed? But, aside from this, it is impossible to assume, in making a judicial finding of what it would cost to acquire the property, that the company would be compelled to pay more than its fair market value. It is equipped with the governmental power of eminent domain. In view of its public purpose, it has been granted this privilege in order to prevent advantage being taken of its necessities. It would be free to stand upon its legal rights and it cannot be supposed that they would be disregarded.

4. "It is urged that in this view the company would be bound to pay the 'railroad value' of the property. But supposing the railroad to be obliterated and the lands to be held by others, the owner of each parcel would be entitled to receive on its condemnation its fair market value for all its available uses and purposes. (United States *v.* Chandler-Dunbar Water Power Co., decided May 26, 1913, 229 U. S., 53.) If, in the case of any such owner his property had a peculiar value or special adaptation for railroad purposes, that would be an element to be considered. (Mississippi, etc., Boom Company *v.* Patterson, 98 U. S., 403; Shoemaker *v.* United States, 147 U. S., 282; United States *v.* Chandler-Dunbar Co., *supra.*) But still the inquiry would be as to the fair market value of the property—as to what the owner had lost, and not what the taker had gained. (Boston Chamber of Commerce *v.* Boston, 217 U. S., 189, 195.) The owner

would not be entitled to demand payment of the amount which the property might be deemed worth to the company, or of an enhanced value by virtue of the purpose for which it was taken, or of an increase over its fair market value, by reason of any added value supposed to result from its combination with tracts acquired from others, so as to make it a part of a continuous railroad right of way held in one ownership. (United States *v.* Chandler-Dunbar Co., *supra*; Boston Chamber of Commerce *v.* Boston, *supra.*) There is no evidence before us from which the amount which would properly be allowable in such condemnation proceedings can be ascertained.

5. "Moreover, it is manifest that an attempt to estimate what would be the actual cost of acquiring the right of way, if the railroad were not there, is to indulge in mere speculation. The railroad has long been established; to it have been linked the activities of agriculture, industry, and trade. Communities have long been dependent upon its service, and their growth and development have been conditioned upon the facilities it has provided. The uses of property in the communities which it serves are to a large degree determined by it. The values of property along its line largely depend upon its existence. It is an integral part of the communal life. The assumption of its non-existence, and at the same time that the values that rest upon it remain unchanged, is impossible and cannot be entertained. The conditions of ownership of the property and the amounts which would have to be paid in acquiring the right of way, supposing the railroad to be removed, are wholly beyond reach of any process of rational determination. The cost of reproduction method is of service in ascertaining the present value of the plant, when it is reasonably applied and when the cost of reproducing the property may be ascertained with a proper degree of certainty. But it does not justify the acceptance of results which depend upon mere conjecture. It is fundamental that the judicial power to declare legislative action invalid upon constitutional grounds is to be exercised only in clear cases. The constitutional invalidity must be manifest, and if it rests upon disputed questions of fact the invalidating facts must be proved. And this is true of asserted value as of other facts.

6. "The evidence in these cases demonstrates that the appraisement of the St. Paul and Minneapolis properties which were accepted by the master were in substance appraisals of what was considered to be the peculiar value of the railroad right of way. Efforts to express the results in the terms of a theory of cost of reproduction fail, as naturally they must, to alter or obscure the essential character of the work undertaken and performed. Presented with an impossible hypothesis, and endeavoring to conform to it, the appraisers—men of ability and experience—were manifestly seeking to give their best judgment as to what the railroad right of way was worth. And doubtless it was believed that it might cost even more to acquire the property, if one attempted to buy into the cities as they now exist and all difficulties that might be imagined as incident to such a 'reproduction' were considered. The railroad right of way was conceived to be a property *sui generis,* 'a large body of land in a continuous ownership,' representing one of the 'highest uses' of property and

possessing an exceptional value. The estimates before us, as approved by the master, with his increase of 25 per cent. in the case of the Duluth property, must be taken to be estimates of the 'railway value' of the land; and whether or not this is conceived of as paid to other owners upon a hypothetical reacquisition of the property is not controlling when we come to the substantial question to be decided.

7. "That question is whether, in determining the fair present value of the property of the railroad company as a basis of its charges to the public, it is entitled to a valuation of its right of way not only in excess of the amount invested in it, but also in excess of the market value of contiguous and similarly situated property. For the purpose of making rates, is its land devoted to the public use to be treated (irrespective of improvements) not only as increasing in value by reason of the activities and general prosperity of the community, but as constantly outstripping in this increase, all neighboring lands of like character devoted to other uses? If rates laid by competent authority, State or national, are otherwise just and reasonable, are they to be held to be unconstitutional and void because they do not permit a return upon an increment so calculated?

8. "It is clear that in ascertaining the present value we are not limited to the consideration of the amount of the actual investment. If that has been reckless or improvident, losses may be sustained which the community does not underwrite. As the company may not be protected in its actual investment, if the value of its property be plainly less, so the making of a just return for the use of the property involves the recognition of its fair value if it be more than its cost. The property is held in private ownership and it is that property, and not the original cost of it, of which the owner may not be deprived without due process of law. But still it is property employed in a public calling, subject to governmental regulation, and while under the guise of such regulation it may not be confiscated; it is equally true that there is attached to its use the condition that charges to the public shall not be unreasonable. And where the inquiry is as to the fair value of the property, in order to determine the reasonableness of the return allowed by the rate-making power, it is not admissible to attribute to the property owned by the carriers a speculative increment of value, over the amount invested in it and beyond the value of similar property owned by others solely by reason of the fact that it is used in the public service. That would be to disregard the essential conditions of the public use and to make the public use destructive of the public right.

9. "The increase sought for 'railway value' in these cases is an increment over all outlays of the carrier and over the values of similar land in the vicinity. It is an increment which cannot be referred to any known criterion, but must rest on a mere expression of judgment which finds no proper test or standard in the transactions of the business world. It is an increment which in the last analysis must rest on an estimate of the value of the railroad use as compared with other business uses; it involves an appreciation of the returns from rates (when rates themselves are in dispute) and a sweeping generalization embracing substantially all the activities of the community. For an allowance of this character there is no warrant.

10. "Assuming that the company is entitled to a reasonable share in the general prosperity of the communities which it serves, and thus to attribute to its property an increase in value, still the increase so allowed, apart from any improvements it may make, cannot properly extend beyond the fair average of the normal market value of land in the vicinity having a similar character. Otherwise we enter the realm of mere conjecture. We therefore hold that it was error to base the estimates of value of the right of way, yards, and terminals upon the so-called railway value of the property. The company would certainly have no ground of complaint if it were allowed a value for these lands equal to the fair average market value of similar land in the vicinity, without additions by the use of multipliers, or otherwise, to cover hypothetical outlays. The allowances made below for a conjectural cost of acquisition and consequential damages must be disapproved; and in this view we also think it was error to add to the amount taken as the present value of the lands the further sums calculated on that value, which were embraced in the items of 'engineering, superintendence, legal expense', 'contingencies', and 'interest during construction.'"

Conclusions to be Drawn from the Minnesota Rate Case.—Careful study of this case seems to indicate that the Court did not intend to exclude from railway lands any of those elements of cost which necessarily must be met in their acquisition; on the contrary, it is distinctly stated that

"It is impossible to assume that the company would be required to pay more than its fair market value. It is equipped with the power of eminent domain. * * * It would be free to stand upon its legal rights and it would not be supposed they would be disregarded."

Thus, the Court makes the cost of acquiring by condemnation the test. The utility cannot claim any more in the reproduction estimate than would be paid were all the land to be condemned, giving the owners its fair market value for all available uses and purposes.

Another point that is strongly brought out is the fact that land valuation must be capable of proof by reference to known and established criteria and must not be based on speculation or hypothesis. Among the paragraphs quoted by the Court from Mr. Cooper's testimony, is the following:

"'Q. * * * There is nothing in any of your exhibits which will show, nor are you now prepared to state, the difference in what might be termed the normal, true, ordinary market value of the lands to the ordinary individual, and the sum which you have fixed as the market value to the railroad company if it were now compelled to purchase? A. That is correct.'"

Again, after discussing all the elements of value which would be allowable in case of condemnation, the Court says:

"There is no evidence before us from which the amount which would be properly allowable in such condemnation proceedings can be ascertained."

and, in the next to the last paragraph quoted:

"The amount of the fair value of the company's land cannot be satisfactorily determined from the evidence."

This decision must be looked on as sounding a strong note of warning against adding elements of value which are hypothetical, or increments which are based on generalization or speculation.

The adoption of a sweeping rule and its application, when "it cannot be referred to any known criterion", and has "no proper test or standard in the transactions of the business world", is not endorsed in this case. The problem in the valuation of lands of the class under consideration is to find such a rule as will apply, as will be capable of direct proof, and as will be supported by the standard of ordinary transactions in the business world and by actual experience in the buying of lands for similar purposes under similar conditions.

Although the decision does not seem to be capable of such an interpretation as would exclude any elements of value which would actually be paid for in acquiring the land, it does unequivocally bar from consideration any intangible values which would attach to the property by reason of its new ownership and new use. No hypothetical "railway value" is to be considered. The decision, throughout the discussion of land values, is full of references to these speculative elements of value and the impossibility of their determination by any known rules. It would appear to be clear that the Courts will not approve any attempt to attach to land values, in connection with the valuation of physical property, "a speculative increment of value, over the amount invested in it and beyond the value of similar property owned by others solely by reason of the fact that it is used in public service."

There is one element of loss to the owner which is not mentioned in the decision, but the Committee feels sure that the omission was not intended to deny the propriety of including the element, because, as seems to be indicated in Paragraphs 6 to 10, the Court satisfied itself with the decision that an attempt had been made to show "railway value", "what the taker had gained", for the land, that this was improper, and that there was no evidence submitted to show what the real value might be, and hence that other questions which might be pertinent were not considered. The element to which reference is made is that of damage to the remaining property by reason of the taking of a part of it—severance damages.

There is a long line of Court decisions in condemnation cases, and some State statutes which sustain the inclusion of this element of

cost wherever condemnation is necessary. It is not believed by the Committee that this decision is to be construed as arbitrarily excluding this element of just compensation, or value to the seller, where it would occur, and would be capable of proper proof.

Although the decision seems to exclude another item of cost to the company—namely, the costs of acquisition—the Committee believes that this exclusion is apparent rather than real, and that a proper estimate of the costs of acquisition, which should be made on a rational basis, the result of experience in or knowledge of similar purchases, would undoubtedly have been approved. The testimony before the Court seemed to include all the elements of cost over "fair value" as "fair value", and then to add to this and resulting sums successive percentages for engineering, etc., contingencies, and interest; all of which appealed to the Court as creating a purely hypothetical or conjectural value.

Therefore, in spite of the quite positive character of the latter half of Paragraph 10, the Committee believes that this wording, taken in connection with the last three sentences of Paragraph 3, the second sentence of Paragraph 4, the well-known interpretation at law of the term "just compensation", and the character of the testimony offered in the Minnesota rate case, does not exclude properly estimated "fair market value", "severance damage" where it would be incurred, or proper "costs of acquisition", from an estimate of the cost of reproduction, however the Court may regard any of these items when finally determining "fair value".

All three are certainly elements of the cost recognized by all persons who have had to do with the purchase of properties for public utilities whether privately or publicly owned. The Court contented itself with showing that the evidence before it was to sustain the value as what the taker would gain, not what the seller would lose; and that this is not a proper basis for cost of reproduction.

The Meaning of the Term "Market Value."—The words "market value" in the ordinary acceptance of the term mean the price of a commodity in the open market, the price at which it is bought and sold.

The market value of land for general purposes, as used in condemnation and similar cases, has been defined many times. As comprehensive and satisfactory a definition as any is that of the Supreme Court of Kansas, as follows (Kansas City, etc., Rd. Co. *vs.* Fisher, 49 Kans., 17):

"The market value means the fair value of the property as between one who wants to purchase and one who wants to sell, not what could be obtained for it under peculiar circumstances when a greater than its fair price could be obtained, nor its speculative value; not a value obtained from the necessities of another; nor on the other hand is it to be limited to that price which the property would bring when forced

off at auction under the hammer. It is what it would bring at a fair public sale when one party wanted to sell and the other to buy."

Mr. Justice Hughes fixed condemnation as the measure.

"It is impossible to assume * * * that the company would be compelled to pay more than its fair market value. It is equipped with the governmental power of eminent domain. * * * The owner of each parcel would be entitled to receive on its condemnation its fair market value for all its available uses and purposes."

What is the measure of damages in condemnation? What would the seller of the land be compelled to take as the fair market value? Lewis in "Eminent Domain", Section 463, states:

"*Measure of damages when entire tract is taken.* This case presents but little difficulty, and, so far as we have observed, there is no difference in the authorities as to the proper measure of damages. A fair equivalent for any entire piece of property is its value in money."

Also, in Section 464:

"*When part is taken, Just Compensation includes damages to the remainder.* Upon this point there is entire unanimity of opinion. The constitutional provision cannot be carried out, in its letter and spirit, by anything short of a just compensation for all the direct damages to the owner of the lot, confined to that lot, by the taking of his land. The paramount law intends that such owner, so far as that lot is in question, shall be put in as good a condition, pecuniarily, by a just compensation, as he would have been in if that lot of land had remained entire, as his own property. How much less is that lot, and its erections thereon remaining, worth to the owner, as property to be used or leased or sold the day after the part was taken, to be used for the purposes designed, than the whole lot intact was the day before such taking (Bangor & Piscataqua R. R. Co. *vs.* McComb, 60 M. E., 290). In considering damages to the remainder however, the whole remainder must be taken into account. If part is damaged and part benefited, the question will be whether the whole is worth less than before the taking."

The same use of the word "just" is to be found in nearly every State Constitution wherein "just compensation" is used to express the measure of damages for taking of property under the right of eminent domain.

The value to be used, therefore, is the fair market value of the property taken and the damages to that not taken, and "just compensation" shall take into account all elements of value heretofore discussed.

The Committee is of the opinion that in estimating cost it is not error to consider each parcel originally acquired, and to attach to it such reproduction cost as would be fixed in condemnation, including severance damages, where severance would actually occur, and that the reproduction cost so found should be accepted as significant. To

assume arbitrarily a rule of valuation, based on the use of hypothetical multiples, and apply it to the entire acreage of lands in a State cannot be sustained. The failure to point out what proportion of lands bear severance damages, and the failure to support by actual recent costs or actual recent experience in the acquisition of similar lands, and the further failure to indicate the relation existing between the price per acre measure when applied to utility lands, many if not most of which have a large element of consequential damages, and the price per acre measure applied to entire tracts taken or tracts sold for general purposes, is likely to be serious and defeat the object of the valuation.

Value to Owner and Taker.—The Element That Must be Excluded in Valuation.—Turning to Boston Chamber of Commerce *v.* Boston (217 U. S., 189, 195), we find the origin of the expression of the quoted paragraph, "as to what the owner had lost, and not what the taker had gained", and the facts in that case clearly indicate that in condemnation cases the inquiry must be, "What has the owner lost?"

It is somewhat difficult to understand that the taker may fairly obtain something with which the owner does not part, but, taken in connection with Paragraphs 478 and 479 of Lewis on "Eminent Domain", and with decisions heretofore quoted, it seems to be quite apparent that Mr. Justice Hughes made what he meant sufficiently clear when he said:

"The owner would not be entitled to demand payment of the amount which the property might be deemed worth to the company, or of an enhanced value by virtue of the purpose for which it was taken, or of an increase over its fair market value, by reason of any added value supposed to result from its combination with tracts acquired from others, so as to make it a part of a continuous railroad right of way held in one ownership."

This language harmonizes with the well-settled principles set forth by Lewis, and shows that there may be something gained by the taker that is not properly a part of the damages which the owner sustains. This additional value is not properly to be included in the reproduction estimate.

The subject is gone into at some length in U. S. *v.* Chandler-Dunbar (229 U. S., pages 79-81), where a strategic value was claimed for certain property. Therein, the Court said:

"That the property may have to the public a greater value than the fair market value, affords no just criterion for estimating what the owner should receive. It is not proper to attribute to it any part of the value which might result from a consideration of its value as a necessary part of a comprehensive system of river improvement which should include the river and the upland upon the shore adjacent. * * * A 'strategic value' might be realized by a price fixed by the necessities of one person buying from another, free to sell or refuse as the price

suited. But in a condemnation proceeding, the value of the property to the Government for its particular use is not a criterion. The owner must be compensated for what is taken from him, but that is done when he is paid its fair market value for all available uses and purposes, Lewis, Eminent Domain, 2d Ed., Sec. 706; Moulton *v.* Newburyport Water Co., 137 Mass., 163, 167; United States *v.* Senfert Bros. Co., 78 Fed. Rep., 520; Alloway *v.* Nashville, 88 Tenn., 510, 514; United States *v.* Honolulu Co., 122 Fed. Rep., 581."

The Committee interprets the decision of the Court to support quite clearly the contention that all elements of value and damages to the seller considered in condemnation must be considered in valuation, but that special values due to increased earning power by reason of a new use are not approved in these decisions. This feature is especially emphasized in City of New York *vs.* William Sage, Jr., (229 U. S., 372).

In this case, the Commissioners appointed by the City reported that:

"The sum of $7 624.45 for lands and buildings and the further sum of $4 324.45 for reservoir availability and adaptability being a grand total of the sum of $11 948.90 is the sum ascertained and determined by us * * * to be paid to the owners of and all persons interested in said land for the taking of the fee thereof, designated * * * as Parcel 733."

The report was confirmed by the Circuit Judge (190 Fed., 413) and by the Circuit Court of Appeals (124 C. C. A., 251, 206 Fed., 369) but was reversed by the U. S. Supreme Court, which said (229 U. S., 372):

"Upon an inspection of the record it appears to us, as the language of the Commissioners on its face suggests, that their report does not mean that the claimant's land had a market value of $11 948.90—that it would have brought that sum at a fair sale—but that they considered the value of the reservoir (site) as a whole and allowed what they thought a fair proportion of the increase, over and above the market value of the lot, to the owner of the land, subject to the opinion of the Court upon the point of law thus raised. * * * But the only explanation of the separation of items by the Commissioners is that they were not prepared to say that the market value of the lot was $11 948.90, seeing that the claimant bought it a few days before for $4 500, but that they thought the additional value gained by the City's act should be taken into account and shared between the City and the owner of the land—a proposition to which we cannot assent (Minnesota Rate Cases, 230 U. S., 352, 451; McGovern *v.* New York, 229 U. S., 363, 372)."

* * * * * * *

"The decisions appear to us to have made the principles plain. No doubt when this class of questions first arose it was said in a general way that adaptability to the purposes for which the land could be used most profitably was to be considered; and that is true. * * * But it is to be considered only so far as the public would have considered

it if the land had been offered for sale in the absence of the City's exercise of the power of eminent domain.

"The fact that the most profitable use could be made only in connection with other land is not conclusive against its being taken into account, if the union of the properties necessary is so practicable that the possibility would affect the market price. * * * But what the owner is entitled to is the value of the property taken, and that means what it fairly may be believed that a purchaser in fair market conditions would have given for it in fact—not what a tribunal at a later date may think a purchaser would have been wise to give, nor a proportion of the advance due to its union with other lots.

"The city is not to be made to pay for any part of what it has added to the land by thus uniting it with other lots if that union would not have been practicable or have been attempted except by the intervention of eminent domain.

"Any rise in value before the taking, not caused by the expectation of that event, is to be allowed, but we repeat, it must be a rise in what a purchaser might be expected to give."

* * * * * *

"The enhanced value of the land as a part of the Ashokan Reservoir depends on the whole land necessary being devoted to that use. * * * If the parcels were not brought together by a taking under eminent domain, the chance of their being united by agreement or purchase in such a way as to be available well might be regarded as too remote and speculative to have any legitimate effect upon the valuation."

This case well illustrates the fact that in condemnation proceedings the owner is not entitled to the enhanced value of the land which comes to it as a part of the enterprise for which it is taken; that is to say, the additional value gained by the company's act of taking the land and combining it with other parcels should not be taken into account, and the owner is not entitled to participate in such additional value so gained. The company is not bound to pay any part of what it adds to the land by uniting it with other tracts. In determining the reproduction cost—what the owners are entitled to receive—adaptability to the purposes for which the land can be used most profitably may be considered, but only so far as the public would have considered such adaptability if the land had been offered for sale in the absence of the company's exercise of the power of eminent domain. The available uses and purposes referred to may not properly include any more than what it may be fairly believed a purchaser under fair market conditions would pay for the land in advance of its union with other lots for more profitable use. Any value which exists before the taking of the land, and which is not caused by the expectation of that event, is to be allowed.

Normal Cost of Public Utility Lands as Compared with General Land Values.—As has already been pointed out, sales of land for

general purposes are made under conditions which are very different from those that prevail in the case of sales for railroad or reservoir lands. In one case, the sale is of the entire parcel, both parties to the transaction being willing parties, the buyer being free to take or leave the bargain. In the other case, the purchaser must take this particular parcel or part thereof and no other. He may condemn, but if he takes only a part, he must include the element of severance and other damages in his price. These considerations lead the Committee to the conclusion that fair comparison can only be made with similar purchases, that is, railroad land costs for inclusion in a valuation by the reproduction method must be determined by a study of railroad purchases of lands of the same class, in the same locality. It may be that in certain districts the cost of lands for railroad right of way exceeds little, or not at all, the cost of lands for farming or other general purposes, while a few miles away the development of the country is such that very heavy severance damages will be incurred, thereby increasing the resulting cost per acre to several times that of the general purpose land. It devolves on the evaluator, therefore, to support his estimate by actual history as to the extent of inclusion of damages, and by actual recent costs of like accumulations of property in the same or contiguous territory or in territory where all general conditions are similar.

That, as a general rule, a right of way for a railroad or a body of lands acquired for a dam or reservoir does cost more per acre or square foot than other lands is clearly shown by a study of records of actual costs of such tracts.

Professor David Friday, in making the land valuation of the Pere Marquette Railroad, in Michigan, cites several instances of land purchases, as follows:

(1).—The right of way from Greenville to Stanton, purchased in 1900, cost $22 435. This includes several $1 considerations and does not include such costs of acquisition as services of real estate agents, registration fees, legal and recording fees, and other similar items of expense. The value of this record, on the basis of contiguous lands, would be only $6 738, manifestly an absurdly low figure in view of the fact that land in this district has increased in value more than 60% since the date of purchase.

(2).—The right of way from Belding to Lowell, purchased at various times between 1892-1900, cost $32 518. The present value, on the basis of adjoining lands, is $13 136. Here, also, the increase in value has been large.

(3).—The right of way from Oak to Delray, purchased in 1891-1892, cost $191 013. The present value, on the basis of adjoining lands, would be $121 120. The proximity of this land to the City of Detroit has increased general values by more than 100% since the acquisition of the right of way.

(4).—The land for the right of way for the new track at New Buffalo, consisting of 199 acres, was purchased in 1911 at an average cost of more than $185 per acre. This is at least three times the unit value of adjoining lands.

The following, also cited by Professor Friday, serve as further examples of the cost of railroad rights of way in various locations and under various conditions:

The Benton Harbor-St. Joe Interurban Road, from Benton Harbor to Coloma, Mich., a distance of 12 miles, bought, in 1910, 100.46 acres for its right of way at an average cost per acre of $267.30. This was bought through a territory which desired the road and in which land was worth from $60 to $100 per acre.

The Milwaukee, Sparta and Northwestern Railway in the State of Wisconsin purchased the 5 127 acres in its right of way and station grounds for $1 129 531. The market value of these lands on the basis of values of adjoining lands was $361 015, or less than one-third the amount actually paid therefor.

The Chicago, Burlington and Quincy Railway bought, some years ago, land in the City of Moline for $112 000. The market value of these lands, as estimated on the basis of adjoining values, was $66 600.

The "Soo" line paid for 3 460 acres in Wisconsin, purchased in extending its road from Glenwood north to the State line and from Thief River Falls west to the State line, the sum of $190 950. The value per acre of land in the immediate vicinity as estimated by the Wisconsin Tax Commission was $19.30; the price paid by the Railroad Company was $55.20, or 2.85 times the ordinary value.

Purchases for the Illinois Central through Mower and Freeborn Counties in Minnesota some years ago, amounting to 228 acres, cost the Railroad $125 per acre, while the adjoining lands were estimated by the Minnesota Railroad and Warehouse Commission as having a value of $49 per acre.

The Hastings and Northwestern Railroad Company, a subsidiary of the Union Pacific Railroad, purchased its right of way between August, 1912, and May, 1914, at a cost of $221 355.06. The value of this land, on the basis of unit values of adjoining land was $96 729.

In 1903, an extended series of investigations of actual considerations paid by railroads for rights of way for new lines, changes of line, and for lands for widening right of way, were made by Mr. Van Ranst Pond and H. E. Riggs, M. Am. Soc. C. E.

These investigations were supported by a large mass of testimony given by registers of deeds, land owners, and others, in the Michigan tax cases. There are very few condemnations in the many hundreds of transfers investigated. Some typical examples of these data follow:

The Jackson and Battle Creek Railway was an electric interurban line, partly paralleling the highways, and for a number of miles being parallel with and adjoining the Michigan Central right of way—all country lands; average considerations to owners in Jackson County, $239.53 per acre; in Calhoun County, $218.74 per acre. Farm land values in these counties range from $60 to $100 per acre, with $75 to $80 per acre as a liberal average.

In Monroe County, Michigan, several lines of road have been built since 1900. This is good farming land worth from $80 to $100 per acre. Considerations (average for the entire County) were paid for railroad lands as follows: Flint and Pere Marquette, $215.21; Toledo and Monroe (electric), $461.13; and the Detroit and Toledo Shore Line, $262.49.

The Grand Trunk Railway made certain changes of its lines near Flint and near Battle Creek, which involved in each instance building several miles of new line. This was far enough away from the old line to get out of the same farms and, except at the extreme ends, there were no complications due to crossing lands already cut. There were no condemnations. The line near Flint, in Genesee County, was entirely across good farm land worth from $100 to $115 per acre. The average paid per acre was $337.56. West of Battle Creek, in Calhoun County, the land was sandy and not high-class, and worth from $60 to $85 per acre. The average consideration was $491.13 per acre. In neither case were values affected by proximity to the cities, as there was no plotting of new additions near the city nor of either cut-off.

In 1896, the Ann Arbor Railroad built a new main line 10 miles north in Washtenaw County. This line left the old line about 3 miles north of Ann Arbor and was several miles west of the old road. It was wholly in farming lands, part of poor quality. Values ranged from $50 to $90 per acre, averaging about $75. The considerations averaged $285 per acre.

The foregoing examples are only a few of the many investigated in Michigan. In these, the railroad lands, no matter how acquired, cost

from two and one-half to six times as much as general lands, due, doubtless, in great measure, to the amount of severance damages paid by the companies, but which elements of cost were not segregated in the work in Michigan.

In none of the examples cited are costs of acquisition or overhead cost included.

Among the illustrations presented by the railroads to the Interstate Commerce Commission in 1915 was a statement showing, for a number of roads in several States, the actual cost of recent acquisitions of railway lands. This statement includes purchases on a total of more than 465 miles of line, and is summarized as follows:

Miles of line.	Total purchase, exclusive of costs of acquisition.	Bare land value, based on general values.	Percentage of land value to total cost.	Other elements of cost.	Percentage of other elements to total cost.
Right of way, 465.4.	$7 868 213	$3 857 783	49	$4 009 831	51
Yards and terminals.	2 005 158	1 144 774	57.2	856 384	42.8

These figures indicate so clearly that railroad purchases exceed purchases for general purposes that it would appear, with a proper presentation as to the percentages of the total acreage affected by other elements of cost, and proper support by reference to actual recent railroad costs under conditions similar to those under investigation, that the proof might be considered to be convincing as to the relation of actual costs to general values of lands.

That lands belonging to other classes of utilities present the same relation to general lands is more difficult of exact illustration on account of the scarcity of reliable records.

Certain records are available, showing the considerations paid for lands and the amounts paid for damages and incidental costs other than land in connection with the acquisition of lands.

New York City—Catskill Water Supply—Cost of Lands.*

Direct cost of 21 327 acres.....	$10 699 946;	average	$509	per	acre
Interest (actual).....	1 648 801	"	78	"	"
Indirect and consequential damages.	294 801	"	14	"	"
Fees, legal, and sundry expense....	4 188 795	"	200	"	"
Total cost of lands.....	$16 808 344;	average	$801	per	acre
Excluding interest.....			$723	"	"

The cost of acquisition, or overheads, excluding interest, aggregates 39.26 per cent.

* Based on Board of Water Supply figures of December 31st, 1914, litigation still pending as to value of 345 acres.

An analysis of this figure is of great interest as showing the same wide range between cost of land and expenses that occur in railroad lands.

Division of work.	Acres.	Cost of land per acre, award.	Expenses per acre.	Expenses, percentage of land cost.	Total per acre cost.
Ashokan Reservoir	15 221	$ 243	$ 155	61.41	$ 398

Kensico Reservoir	3 182	742	404	53.17	1 146
Hill View "	163	8 796	3 871	44.01	12 667
Southern Aqueduct	957	1 987	787	39.66	2 774
City Aqueduct, 90 acres owned by city (bought)	76	6 585	962	15.03	7 547

A recent case in Michigan is very interesting, as throwing light on the cost and value of lands for flowage purposes.

A power company was organized to take over a tract of 17 000 acres of land on the Sturgeon River and build two hydro-electric plants. In 1911, the Duluth, South Shore and Atlantic Railway valuation placed the company's right of way in these counties (Houghton and Baraga) at from $25 to $45 per acre for country lands near the proposed site of the reservoir (about 2 to 5 miles distant). The State's attorney contended for values of from $5 to $10 per acre. Actual land sales throughout that part of the country occupied by reservoir and railroad had ranged from $2 to $10 per acre plus the value of the timber on the lands, or an average, land and timber, of about $12. Under the law, the power company applied to the Michigan Railroad Commission for authority to issue stock and bonds. The opinion, by Commissioner Lawton T. Hemans, is dated June 11th, 1913, and is in part as follows:*

"We believe that the lands described in the application herein should be capitalized at their fair market value, as represented by their initial cost, plus reasonable compensation for the time, energy, and ability bestowed in their acquisition, for the risk involved, and for the use of the capital invested during the interval that must elapse between the inception of the project, in carrying forward negotiations and purchases of distinct parcels, and their final utilization as an assembled whole. It may be contended that the various elements which it is suggested should form the basis of the capitalization allowed for lands and flowage rights are, except as to initial cost, as indefinite as capitalization computed upon any of the bases which the Commission rejects, but the Commission is persuaded that with the various elements stated, disproportion between them, if any exists, becomes more apparent with correspondingly greater certainty in arriving at correct values.

* Northern Michigan Power Company, Orders and Opinions, Michigan Railroad Commission, Vol. 2, No. 1, p. 25.

"It is not to be understood from the foregoing that the Commission holds that the initial cash payment for lands of the character involved is to be considered, of necessity, the all controlling factor in the fixing of their value for purposes of capitalization. Cases can be readily imagined where the cash cost of the physical property embraced in the lands and flowage rights was the least important of the factors enumerated. Indeed, the tract of land under consideration partakes strongly of this character. It is located in a comparatively undeveloped portion of the State, although in close proximity to the copper mining district of the State and possessed of some timber value, the physical features of the greater portion of the tract are such as to make it unsuited for agricultural purposes, compared with like areas alike suitable for water power development in other and more populous districts, the market value of the land is markedly less. The record does not disclose the exact cost of the assembled lands, although it does appear that they have been acquired at prices ranging from ten to one hundred and seventy dollars per acre, and that more than thirty thousand dollars was expended for lands at the last named sum. We are satisfied, from the record, that the sum of five hundred thousand dollars would amply cover the cash outlay for the purchase of the lands. But it appears that the work of acquiring the titles has been in progress since 1902, a period of more than ten years. If interest upon the real estate investment be allowed at six per cent. for half the time, which would seem to be just, it represents the sum of one hundred and fifty thousand dollars. The extended area of the lands necessary for this development have required, as the record discloses, the making of several surveys, the prosecution of legal proceedings, and extended negotiations with more than one hundred separate owners of distinct parcels, who have been found as widely scattered as the boundaries of the Union. Under the laws of this State, the powers of eminent domain are not accorded corporations which seek to develop hydraulic utilities. The last description of land necessary for the purposes of the enterprise must be acquired by purchases before the project is assumed, and while the element of risk involved in the ultimate purchase of so large a body of lands, held under such diversity of ownership, is difficult to estimate in dollars and cents, it is still a risk that is very real, and which enters materially into the value of the property acquired."

The testimony in this case shows that the lands varied in cost from $10 to $170 per acre, averaging about $30. This was more than two and one-half times the average price per acre of lands sold in ordinary tracts. The costs of acquisition, allowing a moderate per diem for the actual time of the promoter plus the expense, were equal to the consideration paid to owners of land.

The examples cited are not exceptions. They are typical of all the cases which have come to the attention of the Committee. There is no general relation between the normal cost of lands acquired for railroad or reservoir purposes, and the market value of farm lands, or other general purpose lands, which can be considered fixed and definite.

Such a relation, however, may be established for limited districts. No rule can be formulated or multiple determined on, which can be universally applied, or even generally applied in any one State.

There have been, in the past, instances of the construction of railroads in timber tracts, or in the western prairie States, in advance of settlement, where the benefits to be derived from the line equalled or in cases far outweighed any damages; and, in such cases, it is easy to conceive that the price paid for the land would not greatly exceed the general average value of lands in the district.

Such conditions rarely exist in an old settled community. For many years the conditions prevailing in all such communities have made the normal cost of railroad and reservoir lands higher when the attempt is made to compute them on the basis of a price per acre.

Costs of Acquisition.—To What Extent Includable in Valuation?—The Interstate Commerce Commission in its classification of Investment in Road and Equipment, effective July 1st, 1914, includes as Items of Expense relating to land the following:

Abstracts
Appraisals
Arbitrators in condemnation cases
Commissions paid to others
Condemnation expenses including Court costs and special counsel fees
Damages to property of others
Deferred payments for right of way
Ditches for waterways when part of consideration
Judgments and decreed costs to clear or defend titles
Notarial fees
Plats
Premiums on condemnation bonds
Recording deeds
Payments for relinquishments of cattle passes and other rights
Removal and relocation of buildings and other structures not purchased
Rent of land when part of consideration for purchase
Right-of-way agents' compensation when engaged solely in acquiring right of way
Taxes accrued and assumed at the time of purchase.

Every one of these items is a necessary expense, not all incurred in connection with every parcel, but every parcel involving some of them, and all are chargeable to capital account as a legitimate cost.

The amount is considerable, in some cases a very large percentage of the purchase price of the parcel of land, but it is somewhat difficult to compute, for when it is reduced to a per acre basis or a percentage of cost basis it is extremely variable. The cost of condemning, or acquiring by purchase, a small fragment of land one-tenth of an acre in area may be as great as the cost of similarly acquiring a farm of many acres.

Examples of actual cost of acquisition of lands are of value as showing the extreme variations in percentage and per acre rates of such costs.

Land Purchases of the Buffalo, Rochester and Pittsburgh Railway.

Year ending June 30th.	No. of parcels.	Total acres.	Consideration for land.	Total costs of acquisition.	Cost of Acquisition: Percentage of consideration.	Per acre.	Per parcel.
1910.....	35	165.789	$20 086	$5 828	2.9	$35.30	$166
1911.....	16	58.694	16 604	1 521	9.1	26.00	95
1912.....	29	60.732	33 506	1 718	5.1	26.50	59
1913.....	63	109.705	73 469	3 486	4.7	31.70	55
1914.....	24	28.730	50 292	3 677	7.3	126.40	153
Total and average.	167	423.646	$193 958	$16 231	8.38	$38.31	$97

These variations in costs of acquisition in percentages from less than 5 to 29, in cost per acre from $26 to $126, in cost per parcel from $55 to $166, are such as to show the necessity of careful investigation of varying local conditions before fixing the estimated amounts.

Land purchases of the Chicago and Northwestern, on one of its new lines, show ratios as follows: 3 620.41 acres; land consideration, $594 169; expense, $72 685; being 7.62%, or $20 per acre.

Statistics presented by Mr. Thomas W. Hulme, in the argument recently held before the Interstate Commerce Commission, show purchases by twenty different corporations for forty-five different pieces of construction. The percentages vary from a minimum of 0.86 to a maximum of 38.4.

Total consideration, all lines, $8 389 730.
Costs of acquisition, $452 656, average 5.4 per cent.

Water-works properties afford an illustration of a class of properties carrying a high cost of acquisition. This is shown by the land costs of the New York City Catskill water supply.* The whole matter may be briefly summarized, as follows:

Amount of awards for land, including payments for land purchased.....	$10 669 946
Awards for indirect damages.....	135 007
Estimated awards for land and damages during 1915, proportionate part of $500 000	323 000
Total payments for land and damages.....	$11 127 953

* Information furnished and arranged by Allen Hazen, M. Am. Soc. C. E., from records and published reports and with the aid of engineers of the Department.

Brought forward		$11 127 953
Expenses of acquiring land not including interest, as per Auditor's report	$4 188 795	
Do. in connection with damages awards	159 794	
Do. in connection with estimated awards during 1915, proportionate part of $500 000	127 000	
Total expenses		$4 475 589
Sum, being the cost of land, with expenses of acquiring it, but not including interest		$15 603 542
Interest on awards allowed by Commissioners and included in the Auditor's report, as part of the cost of land	$1 648 802	
Estimated interest on awards allowed for 1915, proportionate part of $500 000	50 000	
Total interest on awards		$1 698 802
Total actual payments for property to January 1st, 1916, including an estimate of $500 000 for payments in 1915		$17 302 344
Cost of carrying, after acquiring, up to the time when the system is to be put in service, taken as January 1st, 1916:		
Taxes paid	$216 534	
Taxes estimated for 1915	25 000	
Interest on amounts paid to January 1st, 1916, at 4.15%	3 746 652	
Total carrying charges		$3 988 186
Total cost of land and damages, with carrying charges up to date of first use of property, January 1st, 1916		$21 300 530

Calculating the percentages corresponding to these figures, it appears that the expenses of condemnation amounted to 40.1% of the awards and costs; that the interest on the awards allowed by the Commissions and included by the Auditor as part of the cost of the

land amounted to 10.85% of the awards and expenses; that the taxes paid by the city amounted to 1.5% of the cost of the preceding items; and that the interest on the various payments, from the dates of the payments until the property is put into use on January 1st, 1916, will amount to 21.3 per cent.

As a result of all these charges, the cost of the land to the city, with carrying charges to the date of first use, is 91.3% greater than the purchase prices and awards. In other words, the overhead charges on the land are 91.3 per cent.

The expenses of acquiring land as stated by the Auditor, in the sum of $4 188 795, are given below.

This particular case represents the acquisition of land by a city under a law which proved in its execution to be unusually burdensome. It is of value for illustrative purposes, on account of the prominent character of the work and the detail as to costs.

The total costs aggregated 39.26% of the purchase price, and were:

		Per cent.
Advertising	$433 946.46	4.16
Commissioners' fees	1 062 498.72	9.96
Expenses of Commissioners	79 898.40	0.75
Stenographers and clerks	62 606.70	0.59
Special counsel fees	358 679.20	3.36
Special counsel expenses	27 493.06	0.26
Obtaining orders	8 375.00	0.08
Closing title	1 370.00	0.01
Counsel fees on appeal	3 275.00	0.03
Costs on appeal	4 499.97	0.04
Searching titles	211 138.64	1.98
Preparing abstracts	125 312.50	1.17
Appraisers' fees	482 512.53	4.52
Appraisers' expenses	5 792.72	0.06
Rent of New York office	26 269.40	0.25
Stenographers' services and printing testimony	265 684.24	2.49
Counsel fees of parcel owners	384 405.99	3.60
Expenses and disbursement of parcel owners	261 275.36	2.45
Engineering salaries and expenses	373 760.65	3.50
	$4 188 794.54	39.26

Another detailed statement regarding the acquisition of land by a State commission, under a law which was not burdensome, is afforded by the experience on the Metropolitan Water-Works of Massachusetts. In this case the principal acquisition of land was for the Wachusett

Reservoir, the construction of which was not started until several years after other portions of the work were begun. The policy was followed, therefore, of acquiring this land as it could be obtained by negotiation, without resorting to condemnation except in special cases. Much of the land was acquired in this way, considerably in advance of the needs of the work, at a much lower price than it would have been obtained by condemnation, but with an increase in the charges to taxes and interest during construction. From the accounts of all real estate purchased, from the initiation of the work in 1895 to December 1st, 1909, the following summary is obtained:

Total paid directly for real estate, including mill properties and water rights acquired by negotiation		$3 390 723
Awards for real estate condemned, including interest to the date of payment		170 446
Total direct payments for real estate		$3 561 169
Legal and expert services, including conveyancers, experts, appraisers, and court expenses, in acquiring above real estate, exclusive of counsel fees	$179 944	
Estimated proportion of total administration expenses attributable to real estate	60 000	
Engineering expenses are shown by the accounts to amount to $83 582 for the Wachusett Reservoir alone. Assuming that other real estate acquisition would require the same percentage of engineering expenses, the total would be	104 700	
Estimated expenses for counsel in real estate cases, charged to the general expenses of the State, and, therefore, not included in the water-works accounts	20 000	
Estimated expenses for financing and financial officers, attributable to real estate and charged to the general expenses of the State and, therefore, not included in the water-works accounts	20 000	
Total cost of acquisition		$384 644

Brought forward	$384 644
Total cost of real estate, exclusive of taxes and interest during construction	3 945 813
Taxes during construction	68 182
Interest during construction on Wachusett Reservoir, real estate alone, on the basis of 5% compounded annually, would have amounted to $957 000, or 31% of the expenditures for this real estate, including incidental expenses, to the time when the reservoir was first operated. It is estimated that the interest during construction on other real estate would have increased this sum to	1 000 000
Total cost of real estate	$5 013 995

Calculating the percentages corresponding to the different figures, it appears that the incidental expenses of acquiring the real estate amounted to 10.8% of the direct payments for it; that the taxes paid during the construction of the works amounted to 1.9% of the direct payments; and that the interest on the various payments, from the dates of the payments until the property was put in use, on a 5% basis, would have amounted to 28.1% of the direct payments.

As a result of all these charges, the cost of the real estate, with overhead and carrying charges to the date of the operation of the property, is 40.8% greater than the direct payments for it.

The incidental expenses of 10.8% previously given may be subdivided as follows:

	Amount.	Percentage.
Legal and expert expenses, including counsel fees	$199 944	5.62
Administration	60 000	1.68
Engineering	104 700	2.94
Financial expenses	20 000	0.56
Totals	$384 644	10.80

The records of the Metropolitan Water-Works show the relation between the value of the real estate of the Wachusett Reservoir, exclusive of mill property, for general purposes, and the sums which were paid for it.

Before deciding on the project, an estimate of cost of the required real estate was made. To obtain a basis for this estimate, local experts were secured in each town, who went over all the lands, parcel by parcel, appraising the value of land and buildings separately. Their instructions were to value the property very liberally, and the results

obtained were much above its value as determined by sales which had been made about that time. Some of the experts owned property which would be taken for the reservoir. The assessed valuations in this district are supposed to be well up toward the full value of the property, but the value fixed by the experts was one and three-quarter times the assessed value of the property. As a result of the appraisal by the experts, the aggregate valuation obtained was, as follows:

Land, 4 772 acres.....	$244 000	
Buildings	453 000	$697 000

The cost of acquiring the same property, exclusive of overhead charges, was $1 182 000, equal to $485 000, or 69% in excess of the original liberal appraisal of the value.

It is to be noted that this is a case where the appraised general value of the buildings was nearly twice that of the land. The accounts do not show a separation between the amounts paid for buildings and land, but if these amounts could be obtained, they would show that the sums paid on account of the land, in excess of the appraised value, would be a large part of the $485 000 excess, for the reason that it is difficult to sustain a claim for the value of a building much in excess of its value for general purposes.

The 69% previously stated is, therefore, probably much more than the excess cost of the buildings, and much less than the excess cost of the land, over their values for general purposes. It is to be noted, also, that in the acquisition of this property most of the land was taken in whole tracts or parcels, so that there were no severance damages in connection with such portions of the property.

The accounts do not show the sums paid for strips of land taken for aqueducts or pipe lines in comparison with general land values, but the original estimate of the cost of these strips was obtained by multiplying the general value of the land by six, and adding a percentage for overhead charges. The actual cost corresponded very nearly to the estimate.

An illustration which is in marked contrast to the New York Catskill water supply is that of a railroad line in friendly territory, and is as follows:

LAND PURCHASES.

Details of Knife River Branch, N. Dak., Northern Pacific Railway.

	Mercer County, N. Dak.	Dunn County, N. Dak.
Valuation of naked land per acre, made by real estate men and bankers, not by employees.....	$22.07	$22.13
Total	$15 709.42	$12 065.12

	Mercer County, N. Dak.	Dunn County, N. Dak.
Total number of deeds	86	63
Total acres conveyed	784.97	615.55
Average acres per transfer	9.12	9.77
Total consideration	$24 460.	$17 106
Average consideration per acre	$35.00	27.80
Total number of considerations	4	None
Acres condemned	70.83	....
Award in condemnation cases	$1 966.52	....
Average per acre, award	$27.70	....

Summary, both Counties:

Total naked land value	$27 774.54	62.32%
All other elements of value	16 791.89	37.68%
Total purchase price	$44 566.43	100%
Expense of acquisition	$9 258.79	
Percentage expense of acquisition to purchase price	20.77	

Expense of Acquisition:

		Average per deed.	Average per acre.
Services and expenses, right of way agents	$6 790.75	$46.19	$4.85
Services and expenses of attorneys.	705.69	4.80	0.50
Costs of abstracts and opinions of title	1 227.80	8.35	0.93
Cost of recording deeds	329.55	2.24	0.23
Automobile hire	205.00	1.40	0.15
	$9 258.79	$62.98	$6.66

This case affords an illustration of the extremely favorable cost of acquisition. The line was desired by the people. There was but little contest, as two of the condemnation cases were to acquire land owned by the State of North Dakota, the other two being against land companies. Every individual owner was settled with, yet, in spite of these facts, the land cost was $27 774.54, while "other elements" plus cost of acquiring was $26 050.68, or 93.8% of the bare land price.

The conclusion to be drawn from a study of all the figures available to the Committee is that costs of acquisition, like the element of damages in the consideration, are variable, that each valuation must stand by itself, and that, in fixing a figure for land reproduction, the appraiser must take into account all special local conditions. It is perfectly clear that no general average percentage which is universally applicable is to be derived from these figures.

Conclusions.—Cost of Reproducing Land Holdings.—Separate parcels of land, such as one or two lots, or a tract of not unusual size not connected with other lands by the utility in a strip or body, and where freedom of choice in selection may be exercised, should be valued on the same basis as other lands in the vicinity used for general purposes, plus a reasonable allowance for costs of acquisition and other proper overhead costs. The normal market value of parcels of like size, character, and availability, in the immediate vicinity should be accepted as a basis for reproduction cost determination.

Where large tracts have been acquired, made up of a number of separate entire parcels, the history of the transaction should be completely investigated and allowance made in the estimate for costs of acquisition and costs of vacation of streets or acquisition of other rights incident to the use of the property as a whole. Such further allowances should be made, as may seem to be justified by experience, to cover excess costs over and beyond the normal market values which existed at the beginning of the project and were due to fluctuations of price or other causes beyond control. Normal market values of similar and near-by property as of the time of appraisal should be the basis, with such additions as are warranted by the investigation in each case.

In the consideration of values of lands, such as rights of way for a railroad, an electric railroad, an aqueduct, or other like property, or, such as lands for a water-works or an hydro-electric reservoir, freedom of choice is restricted, and where all the land must be acquired, radically different methods must prevail.

In the valuation of lands of this class, a clear distinction should be made between:

(*a*) Lands where the entire tract or parcel is taken and there is no element of severance damages.
(*b*) Lands where only a portion of the tract is taken and where the element of severance damages is present,

and the extent of lands of both classes should be shown.

Historic conditions, where ascertainable, should be given due weight in fixing the extent and character of the severance. The estimate of reproduction should include a proper figure for such as was actually incurred, but should not include allowance to cover speculative or hypothetical damages on account of changed conditions. All elements of value to the seller, including recognition of all damages to the portions of his property not taken, which would prevail in the case of condemnation of the lands under reproduction, should be considered.

A determination of the relation existing between actual recent acquisition costs and the normal market value of the lands out of

which the strip or parcel was taken at the time of acquisition is undoubtedly possible in many cases. It would seem that where such relation can be determined, its use in connection with the normal market values of these or similar lands at the time of appraisal should establish a reasonable cost of reproduction.

There must be kept in mind the fact that no general rule can be established capable of universal application. Conditions that will apply in the acquisition of railroad lands in a large city, or in a fully developed rural community where lands are subdivided into relatively small tracts and with many improvements upon them, may not be at all applicable in districts where lands are held in large tracts with few improvements, such as grazing districts or a heavily timbered district.

The determination of the figure to be used must be based on full consideration of present normal values of general purpose lands, recent purchases by the same or other companies of similar lands in the vicinity or in districts of like characteristics, the extent to which damages enter into the cost of lands, and the amount and character of costs of acquisition and overhead charges. All elements of costs—normal market values of individual parcels, including improvements thereon, severance and consequential damages, enhanced prices induced by active demand, expenses of acquisition and overhead costs, and any other real items of cost which would be included in case of purchase—should be included in reproduction, but no allowance for special values coming after the acquisition of the property, on account of its new use or on account of a greater earning power under the new use, or any other hypothetical "value", should be included.

Estimates should be based on prices and values as of the time of appraisal, be they higher or lower than those prevailing at the time of original acquisition. The thing sought in reproduction is the fair cost of acquiring the property as of the date of valuation.

The treatment of the valuation of land holdings is not yet thoroughly crystallized, therefore the valuing engineer will do well to confer with counsel upon the interpretation of past Court decisions and the legal principles which are most fairly applicable to the case under review.

Overhead Charges.

General Nature of Overhead Charges.—There are certain expenses, inseparable from the construction of any property, which are a necessary and proper part of its cost, but which are not capable of physical identification after the completion of construction work. These expenses cannot be covered in the estimate of "Cost of Reproduction" by the application of specific unit prices; from their nature they attach to the whole or large parts of the property rather than to any particular units. These are called "Overhead Charges".

If the reproduction estimate is to be complete, and is to include allowances for all the labor that was performed, all services that were rendered, and all expenses that were incurred in the construction of the property under investigation, it is clear that a proper allowance, in some form, must be made for these expenditures.

Recognition of Overhead Charges by Courts and Commissions.— Overhead charges in one form or another have been allowed in all past valuations. Commissions have recognized their propriety, and Courts have endorsed their allowance.

One of the most recent cases involving the allowance was the Des Moines Gas Company case. A part of the decision (238 U. S., 153) is quoted as supporting the argument of the Committee that these allowances should be made in amount sufficient to cover all real elements of overhead costs, and no more.

"What is called in this summary 'the present value of physical property', the report shows was arrived at by the Master in the manner following:

"He first found what he thought was the base value of the property, *i. e.*, 'what it would cost to produce it at the present time new, without adding thereto any overhead charges'. This figure he fixed at $1 975 026. To this he added overhead charges, 15 per cent., $296 254. From this he deducted depreciation, $333 878, leaving as the value of the property thus ascertained, $1 937 402."

Mr. Justice Day further said:

"These items of expense in development are often called overhead charges, for which, as we have already seen, the Master allowed 15 per cent. upon the base value (exclusive of real estate), or $296 254, in addition to his allowance of $6 923 for organization expenses. Of these charges the Master said:

"'In reaching the physical value of the plant in question by the process of reproduction, it is necessary to bear in mind that the present value thereof represents much more than the machinery therein, the labor of installing and constructing them, and putting them in place to perform their various functions, ready for the manufacture and distribution of gas to its customers. Were the City of Des Moines without such a plant, and such a one as the Complainant now owns was proposed, it would be found that much more than the mere cost of labor and material would be expended. Such expenditures are termed overhead charges, and are as follows':

"'1. Time and money expended in the promotion of the enterprise, in the organization of the company and interesting capital therein, including, also, legal expenses, obtaining the necessary franchise, as well as the costs of incorporating the company.'

"'2. Then a competent engineer must be employed to prepare the plans and specifications for the plant, and make the necessary surveys, and when the work began, to superintend the construction thereof, and see that it is done properly and according to plans and specifica-

tions. The successful operation of the plant depends largely upon its proper construction.'

"'3. Then losses arising from accidents and injuries to workmen as well as the material during its construction, which is such an amount as the cost of insuring against such losses, which is between 1 and 2 per cent.'

"'4. Contingencies are such expenditures as arise from the lack of foresight and care in preparing the plans and specifications. No matter how carefully the engineer may prepare them, such expenditures invariably arise. Mr. Alvord testified that his allowance therefor would depend very much upon his knowledge of the engineer who prepared them, but that no matter who prepared them, they would invariably occur, and an allowance should be made therefor. The careful and thorough inventory in this case reduces very greatly the allowance therefor.'

"'5. The cost of administration, which includes the time and money expended by the parties who are engaged in the enterprise, purchasing the material, procuring the money for their payment as needed, and generally superintending the entire enterprise during the construction of the plant.'

"'6. It is estimated that it would take three years to complete the plant in question, and that at least one-half the time and money invested therein would give no return, and that a loss of interest would result therefrom and that such loss would be included in the overhead charges.'

"'7. Taxes during the construction.'

"'The latter is regarded by me as very questionable. It is in a certain sense making taxes an asset rather than a liability, and the amount is so vague and uncertain that it has been given very little consideration and weight in fixing the overhead charges. Either the money or the property should pay taxes.'

"'It must be borne in mind that these expenditures are all made during the promotion and construction of the plant, and are necessarily a part of the cost thereof. No overhead charges that do not inhere in and add to the cost thereof, should be allowed as a part of its physical value. It is not a question of what was actually expended therefor in the plant in question, but what would it cost to reproduce a similar plant at the present time.'"

In the actual construction of any property the expenses properly includible under "Overhead Charges" are actual physical costs of construction. They are in no sense intangible or non-physical values; they are not to be confused with development expense, as defined by the Committee, or going value; and must be set up as part of the physical property itself.

The late Judge R. W. Taylor, acting as arbitrator in the Cleveland Street Railway franchise hearing, said:

"Overhead charges as I have used that term and applied it to this situation means only those things for which money has been spent in the necessary work of constructing the property and putting it

into operation * * *. What I want to emphasize is that every dollar of overhead charge which is allowed for by me is a dollar that is necessarily spent in the production of the physical property."

What is true in this respect of an actual construction is also true of a reproduction estimate.

Expenses to be Provided for:

Among the expenditures which must be provided for, and classed as overhead charges are:

(*a*)—Cost of promotion;

(*b*)—Cost of financing and securing the necessary capital with which to carry out the enterprise;

(*c*)—Cost of organization, including the incorporation and organization of the company, securing of franchises, and other like expenditures;

(*d*)—Engineering, including the making of the preliminary investigations and plans, plans for the construction of the entire property, the engineering supervision of all construction and other work involved in the development of a property, except such direct supervision as may properly be included in the unit prices of various property units, or as specific charge against some particular schedule or group of units;

(*e*)—Administration, including salaries for general officers, agents, accountants, clerks, and other assistants, not included in the engineering and legal departments, and all administration expenses;

(*f*)—Legal, including salaries and expenses of law officials and costs of litigation which, depending on the character of the property and its location, may be a comparatively minor item or a very large one;

(*g*)—Interest during the period of construction on money borrowed, or on money invested in the property by its owners;

(*h*)—Taxes and insurance during construction;

(*i*)—Contingencies representing expenditures which cannot be foreseen but which from one cause or another are always of considerable size in the construction or reproduction cost estimate of any great enterprise.

These expenditures, and in some cases others of like character, are all involved in greater or less amounts in the construction of every property. They are represented by no physical property item which can be weighed or measured. They attach to the property as a whole.

Reasonable amounts can be determined for each property by a study of the history and accounting records of that property and

of other similar properties similarly located and built under like conditions.

It is a fundamental principle of valuation recognized by the Courts and commissions, and accepted by this Committee, that under normal circumstances the cost of recently created property furnishes the best basis for determining the reproduction cost of such property.

The Committee recognizes the value of the study of overhead expenses, incurred in connection with the construction of properties similar to the one under consideration, but it does not endorse the inclusion of any allowance which does not represent a legitimate expenditure of money or service in connection with the creation of the property under valuation, merely because such expenditures have been incurred for other properties. It does, however, endorse the inclusion of sufficient allowances to cover all legitimate expenditures, and it favors the use of the percentage on physical costs or any other method that will give fair and correct allowances.

See also the discussion under the caption "Shall Present or Original Physical Conditions Govern" (pp. 1363 to 1370).

Auxiliary or Collateral Costs.—Some engineers, particularly on the Pacific Slope, where large public works are more often executed by day labor than by contract, are in the habit of keeping their cost record data, and hence of estimating the cost of work, by including the so-called "Auxiliary" or "Collateral Costs", comprising incidental road or railroad construction and maintenance during the execution of the work, machinery and plant required, and various other similar classes of expenditures incident to the building of the works, in a percentage, applied to the basic material and labor costs involved in the various units or classes of work. Thus, for instance, though the labor, cement, sand, and gravel costs would be included by these engineers in the unit cost per yard for concrete, the cost, rental, or maintenance of the machinery used in the mixing of the concrete, the cost of the construction and scrapping after the completion of the work of the bins, railroad tracks, towers or travelers of one kind or another, used in the mixing, delivery, and placing of the concrete, would be included in the percentage applied to the above stated unit costs to cover so-called "Auxiliary" or "Collateral Costs". In this report it is assumed that the auxiliary and collateral costs are included in the basic unit prices.

Character of the Items Classed as Overhead Charges.—It is deemed proper by the Committee to present the considerations which prevail in the allowance of various items of overhead charges, some examples of actual costs and allowances under each head, and some of the more authoritative decisions approving such allowances.

(*a*)—*The Cost of Promotion.*—The period prior to the commencement of actual construction of physical properties is, in the case of

most properties, divided into two parts: the period of promotion and the period of corporate organization after the promotion has been brought to a successful issue.

It is clear that the amount of money actually spent in promotion may have a wide range. In the case of such properties as hydro-electric power developments, years of time and large sums of money may be required to secure title to lands and flowages and to bring the project to such form as to justify the attempt to raise funds for actual construction. Other properties may involve but little expense or but little outlay or money. Still other properties may have a large or small outlay on the initial construction, but the major part of the property, developing after operation of the pioneer lines, and built as additions to an existing operating property, may have very little actual cost of promotion.

The argument supporting the allowance of cost of promotion is ably stated in the decision of the Michigan Railroad Commission in the hearing on the application of the Northern Michigan Power Company for authority to issue securities. The decision, written by Commissioner Lawton T. Hemans, discusses "Cost of Promotion", in connection with the cost of acquisition of lands for hydraulic purposes, as follows (19 A. T. and T. Co. Com. L-253-254, June 11th, 1913):

"Another item which it seems to the Commission is properly included in the value of lands for hydraulic purposes, under the Commission's general designation of 'reasonable compensation for the time, energy and ability bestowed in their acquisition', is the item quite generally denominated 'promoter's profit', but which this Commission believes would be more truly descriptive if denominated 'cost of promotion'. The man who devotes his genius to enlisting support for great enterprises of public benefit, which his clearer foresight and keener vision has first perceived in the great world of material development, has performed services quite as valuable to the public as the engineer who later makes computations, plans and specifications, or the man who in any other position contributes to the creation of the utility.

"In passing upon the value of services of this character, the New York Public Service Commission has said that such services 'should be fairly and even liberally rewarded by the public which receives the benefit of these works. Such rewards, however, should be put upon a clear basis of business principles, should be of sufficient magnitude to encourage rather than discourage enterprise, and should not be so great as to make an exorbitant demand which is perpetual in its nature upon the community to be served. They are to be treated simply as just payments for services performed for the corporation, which services are valuable and in many cases even indispensable. Such services should be paid for upon the basis of what they are fairly worth, having regard to all the circumstances of the case'. (*In re* application, Rochester, Corning, Elmira Traction Co., 1 P. S. C., 2d D., N. Y., 166.)

"In the above case the award was made upon the basis of five per cent. on the entire cost of the enterprise, which had a total cost approximating seven million dollars. Other awards have been made by the New York Commission of varying percentages upon the estimated cost of the particular utility.

"In the matter under consideration, request is made to include in capitalization as compensation for promotion, two and one-half per cent. on the estimated cost. The Commission is persuaded that in cases of this character the item of cost of promotion attaches peculiarly to the lands and flowage rights of the development, for, if it is to be justified, as we have indicated our belief it should be, as compensation for a peculiar service incident to every comprehensive scheme of material development, then it should in principle inure to the value of the thing in relation to which the particular service was rendered. It should be compensation to the pioneer, rather than to those who claim neither originality of conception or to have assumed any of the risks of development."

That this element of cost is recognized by the Interstate Commerce Commission is shown by the provision, in the account designated as "Organization Expenses" for

"* * * Cost of preparing and distributing prospectuses; cost of soliciting subscriptions for stock; cash fees paid to promoters, and the actual cash value (at the time of the organization) of securities paid to promoters for their service in organizing the enterprise."

Examples of actual costs of promotion are difficult to cite, for the reason that the accounting for such costs has been as a rule under the head of general expense, or of organization, and have been merged with other costs which belong properly in organization, administration, or legal expenses.

(*b*)—*The Cost of Financing.*—When the project of the promoter has been investigated and found to be sound, and after a plan for the financing of the company has been adopted, there is incurred considerable expense in connection with the issue and sale of stocks or the issuing and marketing of bonds and the payment of commissions to brokers. There can be no question as to the necessity for such expenditures. They are unavoidable, and should be allowed in proper amount.

Whether discount on securities is an allowable item, is an open question. Discount may be a partial capitalization of the commercial risk had in making the investment, it may be an indication of lack of credit on the part of the company, or it may indicate that the interest rate on the bonds is lower than the conditions of the market would warrant, and the discount is in effect an adjustment of the interest rate or a prepayment of interest. If the company secures the benefit of the low interest rate, it would be unfair to capitalize the discount. Nor would it seem any more fair to capitalize excessive risk or poor credit.

That regulating authorities and Courts are not in perfect accord, is shown by the conflicting opinions quoted.

In a Montana rate case (198 Fed., 1003), Judge Hunt says:

"The master allowed 15 per cent. of $562 715.89, or $84 407.38, as a necessary and usual item of cost of reproduction. There was no evidence offered on behalf of the Railroad Commission tending to dispute the conditions which the witnesses for the complainant said existed generally throughout investing communities, namely, that a railroad, such as the one under investigation, is only able to make its financial arrangements by regarding as a part of the construction cost to which it is subjected a discount representing the difference between the amount derived from the sale of its bonds and the amount which the bonds must eventually cost the company. Recognition of discounts on securities, based upon the considerations just expressed, has been made by the courts. Of course there never could be any allowance whereby a corporation can be allowed to capitalize its own lack of credit; but where the bonds are sold at a reasonable discount, and bear a low rate of interest, it would seem to be the equivalent of selling the bonds at par with a high rate of interest. Here the 15 per cent. seems to be reasonable, the testimony showing that upon such a discount the bonds are put upon an equality in marketable conditions with the bonds of some of the very largest and most successful railroads in the country."

Commissioner Hemans, in the Northern Michigan Power Company case, says:

"The application filed herein makes request for the allowance of an item of 2½ per cent. on the cash cost of construction and physical properties to cover the item of banking and brokerage. Unquestionably every comprehensive development of the character being considered finds it expedient to enlist the services of a reputable broker who must be compensated for the investigation he shall make into the basis of the securities, which, if found satisfactory and desirable, he shall recommend to his clientage, but it is a service that is incidental to the sale of the securities or the borrowing of capital. It is an item most intimately connected with bank discount which is in part the rate which a given concern must pay for its loans. We believe that under prevailing practices, in view of the discount at which it is desired that the bonds to be authorized herein may be sold and at which like securities are sold, there is no justification for the inclusion of this item in capitalization, but that it should be included with the bond discount and ultimately extinguished by amortization from the profits of operation."

In the Des Moines gas case (238 U. S., 153), already quoted, Mr. Justice Day quotes the Master, as follows:

"Time and money expended in the promotion of the enterprise in the organization of the company and interesting capital therein, including also legal expenses, obtaining the necessary franchise as well as the costs of incorporating the company."

The Committee is of the opinion that the cost of financing should include all fair costs for interesting capital and issuing and marketing securities. Discount on securities should not be included in capital, but should be amortized over the period of the life of the securities. The fair cost of financing will depend on the probable rate of return, the credit of the promoters, and the degree of hazard attending the project. If a sufficiently high rate of return is assured and the credit of the promoters is good, the cost of financing should be low, little more than an ordinary brokerage rate. Poor credit should not be considered in estimating cost of reproduction, but probable rate of return and the hazard of the enterprise should be considered, and the fair cost of financing estimated as affected thereby.

(*c*)—*The Cost of Organization.*—Under this caption is included a class of expenditures common to all properties, distinct from "Cost of Promotion" in that they usually follow the promotion, and are incurred after the project is assured. There may be many cases in which they merge with the cost of promotion. There are undoubtedly some cases where "Cost of Promotion", "Cost of Financing", and "Cost of Organization" may all be includible under the head of organization. The class of expenses specifically referred to includes costs connected with incorporation and securing a charter, cost of securing franchise, local grants, consents of property owners, consents of the Government, as in case of construction over or under navigable waterways, and all other expenses connected with the organization of the company which is to build the property, and the securing of all the necessary rights, grants, and privileges necessary to permit it to proceed with actual construction.

In Bonbright *vs.* Geary (210 Fed., 44), already quoted, there were included "The legal expenses of organization."

In the Des Moines gas case (236 U. S., 153) there were included "legal expenses obtaining the necessary franchise, as well as the costs of incorporating the company."

In the Knoxville case (212 U. S., 1) the sum of $10 000 was allowed for "Organization, Promotion, etc." The Court assumed this to be a proper allowance without deciding.

(*d*)—*Engineering.*—As an "Overhead Charge" there should be included all engineering costs not capable of specific assignment to property units or special parts of the property.

The general engineering charge, in the case of most properties, is a very considerable item, in some cases amounting to a large percentage. The percentage differs with the character of the works and with the care and skill exercised in their construction.

In the case of a railroad property, general engineering includible as an "Overhead Charge" would cover all the reconnaissance or general investigation of the territory through which the line was to run,

the preliminary surveys, the final location, the general supervision of the chief engineer and assistants whose time is devoted to general, not specific, work, all services of consulting engineers not capable of definite assignment to specific units of property, and much of the expense of the office staff of the chief engineer's office.

In the case of most old properties, it is difficult to draw exact lines between these general engineering expenses and the engineering and inspection during construction, and in many instances it may be desirable to include all engineering as an overhead charge.

In connection with a water-works property, large expenditures must be made for investigations of drainage areas, general surveys, plans and specifications, and general supervision of all construction.

In the illustrations cited of actual engineering costs, no attempt has been made to segregate general engineering charges and direct supervision, all preliminary, general and direct charges being lumped. In case the segregation can be made, it will be found in every case that the overhead charge for general engineering is a very considerable item, which cannot be overlooked or dismissed because of charges to direct supervision.

Examples of actual costs of engineering indicate that there is a rather wide range in the percentage, even on the same kinds of property, due to the presence or absence of a large number of property units which carry high costs of direct supervision. This goes far toward supporting the argument of the Committee that these figures should be analyzed.

The construction of an important dam or aqueduct, built in place and requiring skill in designing, and a careful inspection of every part of the work as it is built, requires a larger expenditure for engineering than a large cast-iron pipe line, where the cost of laying the pipes in a trench is but a small percentage of the total cost of the line, and the work progresses so rapidly that the inspection cost is small in proportion to the total cost. The charge to direct supervision would be much greater in one case than in the other, and if such charge be made, general engineering overhead charge will be more nearly comparable with other like properties.

The cost of engineering varies, not only with the class of work, but with the character of the design and method of its execution—whether by day labor or contract, and in the latter case the nature of the contract. Works may be built with little inspection, from crude designs prepared by unskillful engineers, with the result that the cost of works may be large, although the percentage paid for engineering may be small. Works skillfully designed and efficiently constructed imply a larger cost for engineering, which should be recognized in any valuation when the works give evidence of such skill and efficiency.

(*e*)—*Administration.*—Under this head should be included all allowances to cover the salaries and expenses of executive officers during the period of construction. Also all clerks and other employees, office rent, and expenses in connection with the supervising, accounting, and other offices, except law or engineering.

This allowance should cover, when necessary, all general police and sanitary department employees.

These expenses, like those for engineering, vary, depending on the character and location of the work, legal requirements, and methods of construction followed.

As accounting records have been kept in the past, they are difficult of exact analysis by examination of old records of construction, as they have often been merged with other accounts. There has been such a universal recognition of the propriety of the inclusion of an allowance in proper amount that no argument is considered necessary.

(*f*)—*Legal Expense.*—The law expense incident to construction will vary greatly, depending on the character of the work, the population in the territory in which the work is being done, and the laws which control the operations of corporations as to securing rights or as to construction.

One property may be situated so that few if any obstructions are placed in the way of its construction, and another similar property, in another State, may have not only to pay large sums for legal services necessary to carry out the requirements of statutes and ordinances, but may have to resort to extended litigation before the work is completed. This fact makes necessary a consideration of the history of the property in connection with the allowance for "Legal Expense". This allowance has been made in nearly all past valuations. It is a proper allowance, and should be made in such amount as will adequately cover the expense in each case.

(*g*)—*Interest During Construction.*—Before the construction of works of magnitude can be undertaken, financial arrangements must be made for the advance of the necessary funds. If the period of construction involved be comparatively short, such as one or two years, it has generally been found advantageous, if not necessary, to borrow the entire sum needed in advance of construction. If, on the other hand, the period of construction is a long one, such as from 5 to 10 years, as is true in the case of most large properties, or large parts of properties which have been built during one construction period, instead of developing from small beginnings, it is generally found advantageous to make arrangements for the advance of stated sums at different times during the construction period. Generally, bankers and underwriting syndicates prefer, however, to make arrangements on the basis of purchase of the entire bond issue, though the bonds be delivered at stated intervals in blocks, and allowance be

made for repayment of a nominal rate of interest, such as 2% on unexpended bank balances.

Necessary financial arrangements involve the payment during the construction period of interest on the funds borrowed, or advanced by the owner of the property. It is logical to include these interest payments in the construction cost of the property up to the time when the workable units of the plant are put into actual revenue-producing operation; then the interest payments involved by the investment in the unit of operating property should be accounted in development-expense during the period involved in the acquisition or establishment of the business to the point where the earnings are sufficient to meet the fixed charges, as well as the operating expenses and depreciation allowance; thereafter, the interest payments should be accounted as fixed charges, to be met from the net revenue or divisible earnings of the property.

The determination of the exact time when the different workable units of the property may fairly be assumed to have crossed the dividing line between the "construction-period" and the "physical development-period" is difficult; but this is not a matter of controlling importance if proper allowance be made for the development expense element of the value in the property.

All the arguments for the inclusion of a proper allowance for "Interest" are stated so fully by the Wisconsin Railroad Commission in the Madison Gas and Electric Company case (4 Wis. R. C. R., 501-541, decided March 8th, 1910), that no further discussion appears to be necessary:

"While all these points are interesting, and contribute to an intelligent discussion and determination of the question at issue, it would seem that the interest during construction, correctly allowable in a valuation under ordinary conditions, would be interest at the current rate on the cost of each part of the plant during its construction. The element of cost by reason of interest during construction is one which cannot be escaped. It is present to some extent no matter what the method of financing the construction may be. From the time the investment for construction is made until the completion of the entire plant enables the investment to become active as an integral part of a working whole, there is the element of interest, for that investment is necessarily involved and is necessarily idle until the completion of the plant to a working point. The fact of interest, like the fact of depreciation, is present, no matter what method is employed for financing it. This is as true when the money is furnished by the owners as when it is borrowed by them. The theory upon which such interest rests is sound, and remains so even in isolated cases where the investors decide to charge no interest, and choose to donate the same to the consumers in the way of lower charges for the services rendered. Even if the company let a contract for the complete construction of a plant, to be paid for in no part until wholly

completed to the operating point, interest cost would come in as a part of the contract price, even though not expressly set forth. In that case the contractor would have to ask a higher price to cover the interest cost. Some additional compensation is needed for the investment made by him during the progress of the work and which is necessarily idle until the completion of the plant. Should the company itself construct the plant and be able to arrange to do the entire work on credit—gathering the material, machines and equipment, labor and everything additional needed on credit, to be paid for at the completion of the plant, at the point of operation—the interest cost would nevertheless enter in some form in the entire cost of construction."

It has been the practice on many valuations to assume a period of construction, and to assume that the interest during the period of construction would equal the interest for the entire period on one-half the total cost. In making the assumption as to a proper period of time in which any property could be constructed in connection with the reproduction estimate, due consideration should be given to the actual history of the development of the property, and to the sequence in which the various parts of the property were built or would be built under present-day methods, and making use of existing facilities. Allowances for interest and other overhead charges should be based on actual experience in the construction of the property under investigation, or similar new properties, as far as possible, and not on any such general assumption as stated, as such assumption is likely to give results which would be too small in many instances and excessive in others, and the attempt should be to determine a figure which will be just and equitable in each case.

Some of the earlier railroad appraisals assumed that the property would be produced in short sections, each taking one year for construction, and that an allowance of 3% on the entire cost, or an average of one-half year's interest, would be ample.

While it is undoubtedly true that some properties have been built and opened to traffic in short sections, and have thus carried a small interest charge, and some of these properties would be so built if they were to be reproduced, such an assumption is not applicable to all properties.

From the viewpoint of reproduction under present conditions, interest during construction should be based on carefully prepared construction and financial programmes which will provide for a proper period for reproduction, giving due regard to the history of the enterprise and to the periods of times required for the construction of different portions of the property, as well as a reasonable sequence in the order of reproduction, and will provide fully for all economies. The financial programme should be so adequate as to provide ample funds and materials, as needed during construction, and to eliminate

delays. The rate of interest should be based, not on the financial credit of the property at the time of appraisal, but on the assumption that the property is a new property, and will be developed during the reproduction period assumed, and giving due weight to the hazards attached to each property.

From a strictly historic point of view, the time for which interest during construction should be allowed should be determined on the basis of historic conditions, in the same way as other items entering into the estimate of cost, except that normal present conditions should be used in fixing the rate or rates of interest to be used. Due regard should be given the history of the property as to its effect upon the credit of the company, having in mind that in some existing utilities large parts have been built piecemeal after the original property had been fully established, without the degree of risk and hazard attending the building of the original property, and that in some other utilities the risks attending the development of the additions were fully as great as those attending the construction of the original property. The financial programme should be so adequate as to provide such ample funds and materials as would be needed during the construction periods of the different parts of the property to eliminate delays.

It is not intended by the above statement to suggest that it is necessary to obtain the history of each item added to the original property or used to replace an item which has reached the end of its life, because this would be impracticable and unnecessary; but that the historical basis should be used as a guiding factor in determining the period for which the interest during construction of such items or classes of items should be computed. In other words, the interest during construction allowance for items added to a property from time to time after the original construction should extend only over the period of time required to build each particular item and put it in operation, with a reasonable addition to provide for procuring the money in advance of the beginning of construction.

Interest should then be computed on the various parts of the property, taking into account the time required to construct each and the total time that must elapse from the completion of that part until the operating units of property reach the point of revenue-producing operation.

(*h*)—*Taxes.*—The money paid out for taxes on lands, buildings, materials, and equipment during the period of construction of a utility property would seem to be so obviously a proper charge to capital invested in plant as to require no supporting argument, yet it has not received the unqualified endorsement of the Courts. An illustration may be cited in the case of an electric light and power company in a large mid-western city. The rapid growth of the city and increase of the business necessitated very large increase in the plant facilities, and

it was determined to build a new power station in a new location. A tract of 22 acres was acquired in 1911, and work was at once commenced on preparation of plans. Actual construction was begun in the spring of 1912, and the plant was put in operation during the summer of 1915. During this period 3 full years taxes on the land were paid, and the increase each year in the assessments, on account of the improvements, resulted in a payment during the period of more than four times the tax that would have been paid on the basis of the assessed valuation at the time of purchase. This expense is unavoidable; it is, like interest, a charge that must be provided for, and met out of funds raised for construction. The percentage of the total construction cost may vary on different kinds of property, and care must be taken to make sufficiently full investigations to insure the accuracy of the estimate. The Committee believes that an allowance for taxes, in proper amount, is a fair charge to construction, and should always be included in the reproduction estimate.

(*i*)—*Contingencies.*—Contingencies in construction are those added costs or added items of construction which are made necessary by unforeseen difficulties, or events beyond the control of the builders, or are due to conditions which were not fully determined at the inception of the work. Similarly, the contingencies in an estimate of reproduction are those due to conditions which could not be fully determined at the time of making such estimate of cost and such conditions always prevail, in greater or less degree, depending upon the character of the property and local conditions, the age of the property, the available records, and many other factors.

Contingencies vary in amount with different kinds of property and with different property units. On classes of work in which the contingency item is likely to be large, the proper percentage to allow for contingencies will depend largely on the extent and accuracy of the investigation.

Perhaps no one item of overhead charges on past appraisals has drawn more criticism, and in some instances ridicule, than the allowance for contingencies. The Committee, at the outset of its discussion of the subject, desires to state that no allowance for contingencies is advocated that is not a reasonable one.

It must be emphasized that the allowance for contingencies is an allowance for the unseen and indeterminate cost in reproduction which could not be seen, investigated, and determined in advance of original construction, or at the date of valuation. Many people appear to be unable to realize the fact that it is not possible to see all the things that were done and know all the conditions that accompanied the doing of them when investigating an existing great public utility.

It is fully as difficult to estimate correctly the cost of reproducing an existing property as it is to estimate the cost of producing one

which does not exist, and it may be more difficult. To illustrate, assume one of the large hydro-electric developments or water-works reservoirs. The property is, let us say, 12 or 15 years old. The valuation engineer finds a massive masonry dam, some buildings and equipment capable of definite measurements, and a large lake or water covering several hundred acres. All roads, railroads, and other property surrounding the reservoir are in good condition, and their appearance would not indicate whether they were 12 or 40 years old. The plans, field notebooks, and construction records may be complete, but are more likely not to have been fully preserved, as in many properties the value of old notes and construction records has not been recognized. The problem is to estimate the cost of reproducing the property. There will be many costs which can be covered only by a contingency allowance.

The construction engineer, about to enter upon the construction of such a property, finds in the valley to be occupied all the various properties and constructions that are to be removed, he has available the results of explorations, surveys, soundings, borings, and other investigations which will determine what will be encountered. He has equal knowledge with the valuation engineer as to costs of material, labor, transportation, tools and equipment, and other things needed, and his facilities for accurate estimating are just as good. Yet, in producing the property, he encounters costs not foreseen, due to weather, floods, labor troubles, transportation difficulties, delays, and many other causes.

The contingencies cannot be listed in advance—otherwise they would not be contingencies.

Those who ridicule or omit contingent allowances, or argue that they apply to individual items rather than to the plant costs as a whole, ignore general construction experience. The allowance for contingencies is not an allowance to cover error, as has often been assumed. To some extent contingencies in both construction and reproduction are due to failure to schedule completely all work to be done, but, to a far greater extent, contingencies are due to those unseen, unavoidable, and uncontrollable causes that neither engineer, nor owner, nor contractor can foresee.

Errors of judgment may occasionally add to the cost of construction, and the Committee is of the opinion that a provision for this is justifiable.

The Committee endorses no allowance for contingencies which will add arbitrarily a percentage to a thing that is known and definite; but it does contend for an allowance in all cases except those in which it is certainly known that contingencies would not be incurred.

Character of Contingency Expenses.—Omissions from Schedule.—In both construction and reproduction estimates on large properties, where many thousands of items of property are scattered over a wide area,

or, as in the case of railroads, over hundreds of miles of territory, there are certain to be omissions, not only of minor items, but of large items of property. This applies, not only to property which is capable of easy identification, but to a greater extent to that which was built in connection with the construction, and was essential to it, but which is not in constant use, and of which ownership consequently is finally lost sight of.

Hidden Construction.—Unless the most complete records are available, much of the expense which adds to the cost of foundations of all kinds is apt to be overlooked. Pumping or coffer-dams in some localities, and quicksand or other treacherous material often increasing the size or depth of foundations, makes the cost not only greater per unit but adds largely to actual quantities in excess of the plans. Costs incident to settlement of the surface on marshes, causing a large increase in the fill required, are sometimes included in contingencies, but should be allowed for preferably in the schedule of quantities.

Losses Due to Flood, Storm, or Bad Weather.—Frequent and unavoidable expenses are those due to storms, floods, slides, and wash-outs. There is also the added expense due to freezing or wet weather. The examples of this class are very numerous; hardly any large property has been built which has not had to contend with such difficulties.

Strikes, Labor Troubles, Delays in Delivery of Materials.—Labor troubles are a frequent and expensive occurrence, and, at times, not only delay completion, but add materially to the cost. The non-delivery of material, often necessitating the purchase of small quantities at high prices, or causing expensive delays, is another class of contingency expense which is continually met. Delays are often caused by injunction, or other legal processes or failure to raise the necessary funds as needed, causing, not only extra expense on the work, but loss of interest. The failure of contractors or the abandonment of work by them, is often a serious cause of contingent expense.

Moreover, it often happens on large works that the losses due to interruption of or delay in construction are largely augmented by the loss in efficiency of the working force, incident to building up a partly new organization upon the continuation of construction. The suspension of active work upon the construction of the Los Angeles aqueduct, due to temporary lack of funds, is stated in the report to have caused an additional expense of $250 000.

Construction Outside of the Main Property.—In nearly all large properties it will be found that, either owing to the special location or conditions, or on account of relations with the public or other owners, it is frequently necessary to build considerable work which is in no wise a part of the property under investigation, but is required to readjust existing conditions to permit the work to proceed.

Illustrative Examples of Actual Contingencies.—In building an electric road near Toledo, Ohio, contracts for grading were let at 22 cents per cu. yd. for earth. One section involved a crossing under a railroad. The presence of quicksand and water in the cut made ordinary methods of handling material ineffective, and the contractor failed. The work was completed on the basis of cost plus a percentage, at a cost of 84 cents per cu. yd.

In 1895 the Ann Arbor Railroad was raising an embankment over a swamp. A "sink hole" developed which broke under a freight train, causing not only a loss of many thousands of yards of earth, but damages to property of more than $25 000.

In March, 1905, the flood conditions in Ohio and Indiana were unusually severe. An electric railway bridge over the Maumee River was under construction, and seven high concrete piers were completed ready for superstructure. An ice gorge formed about 2 miles above the bridge, and when it broke two piers were swept away, involving a contingency expense of more than 15% of the entire cost of the bridge.

The Cleveland Railway, in the construction of a new car-house, lost the entire structure in a tornado after more than 70% of the work had been completed.

Elliot Holbrook, M. Am. Soc. C. E., cites examples of contingencies, as follows:

"A piece of construction with which the writer was concerned consumed over two years in construction, while it was expected it would be completed in one season. The result was that owing to increased outlay and greater length of construction period, interest alone was increased by an amount equal to 5 per cent. of the original estimate of total construction cost. A steel bridge near Anoka, estimated to cost $21 000, actually cost $32 000, on account of floods taking the coffer-dam out. Pipe line at Dassel, Minn., estimated to cost $6 600, actually cost $8 300, owing to delays that carried the work into winter, necessitating excavation in frozen ground. Bank widenings in Dakota, estimated to cost $15 000, actually cost $27 000, owing to excessive rains. Change of line from Teton, Mont., to Tunis, Mont., estimated to cost $10 500, actually cost $33 000, on account of a hill giving way and burying a steam shovel. A change of grade, estimated to cost $7 100, actually cost $12 000, owing to slides and wet conditions of material. New yard at Blair, Mont., estimated to cost $41 500, cost $66 700, owing to heavy storms washing out grading and causing delay. Drainage tunnel at Alvin, estimated to cost $16 700, actually cost $23 000, on account of trouble encountered with water. In fact, in the construction of a railroad, there is almost a continuous succession of unforeseen and unforeseeable difficulties that increase the time necessary for construction and the total outlay required."

In the case of subway construction now under way in the City of New York the provision originally made for contingencies, 5%,

has been found to be inadequate, and additional elements of cost have so far developed to indicate that they will amount to upward of 14%, exclusive of the provision that may have to be made for contractor's claims, and further charges for interest on money during construction caused by the non-synchronizing of completed portions of the system.

Many other examples have been cited to the Committee. It is believed that, if it were possible to separate from the bare cost of nearly all large works those items that were actually contingencies, the list might be greatly lengthened. Attention should be directed specially to the fact that nearly all available cost records give total actual construction, but do not give original estimates or originally estimated quantities. To determine contingencies therefor, it is necessary to go in most cases to the original records and make special analyses. This will account for the comparatively small number of cases in which this item of overhead charges has actually been segregated.

The close estimation of cost is an art, of which comparatively few men are masters. In its final analysis it is a matter of judgment, founded upon knowledge and breadth of experience in engineering construction, and discrimination in the determination of the relative effect of different conditions and factors entering into the problem, as well as in the application of well kept records of previously built works. Synthetic cost analysis has some advantages, if limited to the main and readily determinable cost influencing items, though it has the grave danger of implying a degree of accuracy in the results obtained, not actually realized, and the tendency to minimize and under-estimate the elements of hazard and uncertainty, which always exist to a greater or less degree, on any large construction work. Direct comparison with costs of other works, of similar character, under similar conditions, when possible, furnishes the most reliable guide. The method of always comparing the cost of different classes of work, on broad lines, with a previously determined "average-scale", based on general experience under more or less similar conditions, and getting the coefficient or factor, as compared with the average-scale, of each work, is most helpful, particularly to the young engineer.

Allen Hazen, M. Am. Soc. C. E., has discussed this subject in an admirable article on "The Art of Making Rapid and Reliable Preliminary Estimates of Cost",* from which the following paragraphs have been abstracted.

Extra Cost of Novel Designs.—Work on novel designs commonly costs more than work following standard designs. This is true even when well tried methods are first introduced in new places. Such work may be too small to attract bidders from a distance. The unit cost will then overrun anticipated prices. An under-estimate of cost is

Engineering Contracting, March 18th, 1914.

frequently made on work because the estimator fails to realize what a great effect familiarity with the methods of performing work has upon the cost. To realize this one has but to think of the difference between present methods and costs of building tunnels and subways and deep foundations, and the methods and costs of only 10 or 20 years ago. Not only is the risk which the contractor takes now less, but methods which have been thoroughly tried out are at his disposal as well as experienced foremen and laborers, to do the work more economically. For a structure of new or novel design much caution in using prices that may be standard on other kinds of work must be used.

Small Jobs Cost more in Proportion than Large Ones.—Another common cause of under-estimating costs is the use of figures on large pieces of work for estimating small work. The engineer often overlooks the large cost of overhead charges, the waste of labor and the cost of plant caused by organizing a force to perform a small piece of work. He too often forgets that for small work the work must be done by less efficient methods, or the cost of plant prohibits the use of expensive machines. Perhaps the most common case of such underestimating is where the job, although a large one in the aggregate, consists of many small pieces of work of widely varied character. Such a job is troublesome and costly for the contractor, and the experienced man knows it and puts in a corresponding bid.

It must be remembered that bids follow the law of supply and demand; that general slackness in construction work calls out bidders and low prices. The condition of the money market, the cost of materials, and the general opinion of the condition of contract work are of course matters of much importance. It seems scarcely necessary to say that the engineer should know where and how the contractor is to obtain his materials and have a fairly definite idea of the cost, either in dollars and cents or as a comparative figure to other work.

The engineer in estimating should try to look at the work from the standpoint of the contractor, should try to remember that no work runs as smoothly along as the contractor wishes, that labor conditions and other matters often spoil the best laid plans. He should endeavor to keep in mind the various work he has watched or performed and the numerous times when unexpected conditions added largely to the cost.

Generally speaking, estimates on proposed work by men of limited experience are too low, yet it is not unusual for an engineer to be so impressed with the difficulty of a piece of work that he over-estimates the actual cost, and it is more common to find that he has over-estimated the bids of the contractors.

It is of much value to have two methods of arriving at estimates. If an independent check method can be made, even though a rough

one, a failure of the two results to agree often leads to the discovery of serious errors in the application of one or the other method.

Conditions of Success in Estimating.—One of the first requisites for successful estimating is a fair and unprejudiced, and moderately pessimistic mind. The estimator must be alert for new and cheaper processes and methods. and conservatively sceptical concerning their merits. Moreover a successful estimator must have had experience in actual construction. As a general rule an engineer should not make an estimate for a structure that he would not know how to build.

Next, as a requisite to successful estimating, may be mentioned a broad basis of cost records of actual work, more or less similar to that for which estimates are to be made. A good and safe method of using the cost data and adjusting it for application to new conditions is equally important.

And, finally, the estimator must have the will to refuse to make estimates for work that he does not understand.

CHAPTER VI.

DEPRECIATION AND APPRECIATION.

Depreciation in Valuation.—Perhaps there is no single subject in connection with valuation that has caused more trouble than depreciation. This has been due to various causes, perhaps not the least of which has been confusion in the use of the term. Depreciation is sometimes used to mean decretion, which is loss of service life, sometimes to mean the money allowance made in the bookkeeping to offset accruing loss of service life, and sometimes the loss of value existing at any time due to the loss of service life or any other cause. The Committee will use it only as meaning the loss of value or worth of property units which are parts of going concerns. Although this may be due to many causes, the general discussion will include consideration only of those effects which, like wear and tear, age, use, and obsolescence, or inadequacy, bring a physical property unit gradually to the end of its service life.

Another difficulty has been the failure of owners and Courts to comprehend depreciation. Neither of these have realized in the past the necessity for and equity of earning and setting aside allowances to provide for accruing loss of capital due to the accruing, but not yet total, loss of service life of the parts of a property. Nor is this difficulty wholly removed at the present time. In the earliest decisions of the United States Courts bearing on this subject (Union Pacific R. R. Co. *v.* United States, 99 U. S., 402, and United States *v.* Kansas Pacific Ry. Co., 99 U. S., 455, both decided October, 1878), it was held: in the first case, that all expenses for maintenance of the property should be included in operating expense, only cost of original construction and subsequent enlargement and improvement of the works being capital expenditures; and it was even held that ordinary betterments wisely might be made from earnings, apparently without a charge to capital, a practice now generally disapproved by Courts and commissions; and in the second case, that no allowance for depreciation that does not represent cash actually spent can be included in operating expense.

Nineteen years later the Supreme Court of California (in San Diego Water Co. *v.* San Diego, 118 Cal., 556, 1897), mentions depreciation, and in the prevailing opinion given by Justice Van Fleet, reinforced by the concurring opinion of Justice Garouette, distinctly holds that an allowance should not be collected from the rate-payers for it, the concurring opinion saying:

"But such a thing is all wrong, for it results in the consumers of water buying the plant and paying for it in installments."

But it is fair to say that this concurring opinion is based on the notion that such things as tunnels, wells, reservoirs, water rights, and real estate suffer no depreciation;

"* * * there is no wear and tear, no permanent and gradual destruction by use and age. Most of them stand everlasting as the hills."

and that it further admits that the replacement of worn out items is a proper charge to operating expenses, saying:

"If improvements are made in the plant as it stands, as, for example, a new pipe substituted for an old piece of the same size and quality, such charge should be considered operating expenses."

which seems clearly to uphold what will be described later as the replacement method of maintaining property that is supposed to wear out. The decision makes the mistake of finding that certain items of property which do go out of service for one reason or another are "everlasting as the hills."

It is interesting to note that there was a dissenting opinion, handed down by Chief Justice Beatty, which says that after including as current expenses all operating expenses reasonably and properly incurred, taxes, and the cost of current repairs, there should be added to the sum to be collected annually an allowance for a sinking fund sufficient to replace any parts of the plant which, at the end of a term of years, will be so worn out as to require restoration, when this restoration occurs.

The foregoing is introduced because of the appearance, apparently for the first time, of a discussion of the propriety of collecting and setting aside a depreciation allowance, and particularly the approval of such a course as given in the dissenting opinion. A year later, the same Court (in Redlands, etc., Water Co. *v.* Redlands, 212 Cal., 312, 1898) said:

"In a municipal ordinance fixing rates * * * the water company is not entitled to be reimbursed from the income derived from rates, fixed by the ordinance, for interest upon its indebtedness, nor for depreciation of its plant, aside from the amount requisite for its maintenance and repairs during the year."

This decision was consistent with that in the San Diego case, and referred to it, and is here quoted because the United States Supreme Court (in San Diego Land and Town Co. *v.* Jasper, 189 U. S., 439, 1903) referred to this case with approval. And this was as late as 1903. The language used at page 446 of the report is as follows:

"We will say a word about the opposite contention of the appellant that there should have been an allowance for depreciation over and above an allowance for repairs. From a constitutional point of view we see no sufficient evidence that the allowance of six per cent. on the value set by the supervisors, in addition to what was allowed for

repairs, is confiscatory. On the other hand, if the claim is made under the statute, although that would be no ground for bringing the case to this court, it has been decided by the Supreme Court of California that the statute warrants no such claim."

Four years later, at least one Court had seen a light, for (in Perkins *v.* Northern Pacific Ry., 155 Fed., 445, 1907) Judge Lochran, of the Circuit Court of Minnesota, states, among other things:

"It is evident * * * that a railroad, like everything else, will wear out in time, and they have been used so long in this country that there can be a reasonable estimate of the percentage of loss each year from depreciation of the roadbed, culverts, bridges, and rolling stock; that it would be proper to lay aside a reasonable amount to furnish replacements, renewals, and repairs when needed; and that if that was not done the railroad company might soon be in a position in which it could not keep up, with the rates that it was getting, and maintain its property in an efficient state to render such service as the public is entitled to receive from it. Now this is a matter in which the public has an interest as well as the railroad companies and the stockholders of the railroad companies."

"There is a danger that this feeling of selfishness may lead them too far and reduce this compensation so much that it will not enable the railroads to serve them with efficiency—to keep up their roadbed, culverts, bridges, and everything so that they will be entirely safe for the transportation of passengers and freight, and to keep the rolling stock in the best state of efficiency and enable them to provide the best service attainable, and that is exactly what those corporations are required to do. They are required to exercise the highest degree of care in relation to the transportation of passengers, and a high degree of care in relation to the transportation of freight, and it is certainly for the interests of the people that they should be enabled to do this; and it would be a very short sighted policy which would reduce the compensation of these railroads to a degree that would disable them from performing these services fully and fairly for the benefit of the people."

It was not until 1909, however, that the Supreme Court of the United States recognized the character of depreciation and the necessity for collecting an allowance to cover it as it accrues. This recognition appears in the decision handed down by Mr. Justice Moody, in what has come to be known as the Knoxville case. (City of Knoxville *v.* Knoxville Water Co., 212 U. S., 1, decided January 4th, 1909.)

This decision, here quoted somewhat at length, holds that, not only is it proper to set aside periodically an allowance to cover the accruing loss of value of aging property, but that it is the plain duty of operating companies so to do and to collect, from the public served, enough to maintain at all times the value of the investment unimpaired.

It also holds that though the cost of reproduction is one way of ascertaining the present value of a plant, like that of a water company, which has been in use for many years, the test would lead to obviously

incorrect results if the cost of reproduction is not diminished by the depreciation which has come from age and use.

"The cost of reproduction is one way of ascertaining the present value of a plant like that of a water company, but that test would lead to obviously incorrect results, if the cost of reproduction is not diminished by the depreciation which has come from age and use. The company contends that the master, in fixing upon the valuation of the tangible property, did make an allowance for depreciation, but we are unable to agree to this. The master nowhere says that he made allowance for depreciation, and the language of his report is inconsistent with such a reduction. The figures which he adopts are those of a 'fair contractor's price.' The basis of his calculation was the testimony of an opinion witness called from the company. That witness submitted a table, which avowedly showed the cost of reproduction, without allowance for depreciation. The values testified to by him were adopted by the master in the great majority of cases. The witness's valuation of the tangible property was somewhat reduced by the master, but the reductions were not based on the theory of depreciation, but upon a difference of opinion as to reproduction cost.

"The cost of reproduction is not always a fair measure of the present value of a plant which has been in use for many years. The items composing the plant depreciate in value from year to year in varying degree. Some pieces of property, like real estate for instance, depreciate not at all, and sometimes, on the other hand, appreciate in value. But the reservoirs, the mains, the service pipes, structures upon real estate, standpipes, pumps, boilers, meters, tools and appliances of every kind begin to depreciate with more or less rapidity from the moment of their first use. It is not easy to fix at any given time the amount of depreciation of a plant whose component parts are of different ages with different expectation of life. But it is clear that some substantial allowance for depreciation ought to have been made in this case. The officers of the company, *alio intuituo,* estimated what they called 'incomplete depreciation' of this plant (which we understand to be the depreciation of the surviving parts of it still in use) at $77 000 which is 14 per cent. of the master's appraisement of the tangible property.

"A witness called by the city placed the reproduction value of the tangible property at $363 000, and estimated the allowance that should be made for depreciation at $118 000, or 32 per cent. In the view we take of the case, it is not necessary that we should undertake the difficult task of determining exactly how much the master's valuation of the tangible property ought to have been diminished by the depreciation which that property had undergone. It is enough to say that there should have been a considerable diminution, sufficient at least to raise the net income found by the court above 6 per cent. upon the whole valuation thus diminished.

"The company's original case was based upon an elaborate analysis of the cost of construction. To arrive at the present value of the plant, large deductions were made on account of the depreciation. This depreciation was divided into complete depreciation and incomplete depreciation. The complete depreciation represented that part

of the original plant which through destruction or obsolescence had actually perished as useful property. The incomplete depreciation represented the impairment in value of the parts of the plant which remained in existence and were continued in use. It was urgently contended that, in fixing upon a reasonable return, the amounts of complete and incomplete depreciation should be added to the present value of the surviving parts. The court refused to approve this method, and we think properly refused. A water plant, with all its additions, begins to depreciate in value from the moment of its use. Before coming to the question of profit at all, the company is entitled to earn a sufficient sum annually to provide, not only for current repairs, but for making good the depreciation and replacing the parts of the property when they come to the end of their life. The company is not bound to see its property gradually waste, without making provision out of earnings for its replacement. It is entitled to see that from earnings the value of the property invested is kept unimpaired, so that at the end of any given term of years the original investment remains as it was at the beginning. It is not only the right of the company to make such a provision, but it is its duty to its bond and stockholders, and, in case of a public service corporation at least, its plain duty to the public. If a different course were pursued, the only method of providing for replacement of property which has ceased to be useful would be the investment of new capital and the issue of new bonds or stocks. This course would lead to a constantly increasing variance between present value and bond and stock capitalization—a tendency which would inevitably lead to disaster, either to the stockholders or to the public, or both. If, however, a company fails to perform this plain duty and to exact sufficient returns to keep the investment unimpaired, whether this is the result of unwarranted dividends upon over-issues of securities, or of omission to exact proper prices for the output, the fault is its own. When, therefore, a public regulation of its prices comes under question, the true value of the property then employed for the purpose of earning a return cannot be enhanced by a consideration of the errors in management which have been committed in the past."

This decision has been supported in all subsequent decisions of the United States Supreme Court having to do with the matter, and therefore it stands to-day the law in this country. Questions of interpretation have been raised by public utility owners, lower Courts have not all followed the decision literally, and there are certain practical questions arising in connection with the determination of depreciation in the valuation of a property, all of which require careful consideration and will be discussed in this chapter.

Depreciation being defined primarily as loss of value or worth, the depreciation that is of concern in valuation proceedings is that which is measured by the sum that should be deducted from original cost to date or from estimated cost of reproduction new, as a step in finding that which the Courts have called "fair value." The Committee will call this the "depreciation of valuation", or "fair depreciation".

Three Aspects.

The Committee will consider depreciation from three aspects:

1.—The cause—*decretion or loss of service life* of physical property;
2.—The record—*accounting depreciation;*
3.—The amount sought—the *depreciation of valuation,* or *fair depreciation.*

By "decretion" is meant that loss of service life of a physical property, or property unit, or item, which may be estimated by an inspection of the property, considering the history of its past service and the probable character of its future service, the method and character of its maintenance, and all other pertinent facts concerning it. It is the fact of loss of service life, regardless of its effect on value or anything else. Consciously or unconsciously, the result will be expressed as a fraction of the estimated total service life (elapsed life plus expectation of life) of the property, or property unit, or item, and this must be converted into a corresponding fraction of cost, in order to find the loss of value resulting from the decretion. Some minds may not consciously go through the elementary process, but will estimate at once the final money sum.

By "accounting depreciation" is meant that sum which, in the bookkeeping of the owners of the property, has been charged to operating expense and deducted from the capital, either directly or by setting up a reserve, to allow for an estimated or actual depreciation of a property unit or item. A definition conforming to methods prescribed by the Interstate Commerce Commission is the sum charged to operating expense to provide a reserve* to cover the cost less salvage of a given property when it is retired from service. Accounting depreciation may or may not be equivalent to the actual or *fair depreciation* at any time. Whether or not it is approximately equivalent, will depend on the methods used and the accuracy of the forecast of service life of the property units or items.

The "depreciation of valuation" or "fair depreciation" has been defined above.

In valuation discussions, depreciation cannot be treated wholly independently of its cause or of accounting methods, but, so far as possible, the Committee will consider: first, only decretion or the cause; second, only accounting depreciation; and, third, the depreciation of valuation.

Decretion.

Causes of Decretion.—Decretion may be due to use. A machine may have been purchased new, may have been in use a year, may show no signs of wear, and yet experience tells that the machine when new

* For a definition of this term, see p. 1460.

was probably good for only 10 years. One of these years has elapsed; the machine is as valuable in its present output of service as ever it was, but, a year of its life has gone into service, and hence, approximately one-tenth of the life of the machine must be estimated as gone, and therefore decretion exists to that extent. Examination of the particular machine may lead the examiner to estimate that it has still 11 years of service before it, in which case its total life will be estimated at 12 years, and only one-twelfth of its service life will be gone. Examination always should be made, and consideration should be given to the character of past and probable future service, and the method and character of maintenance, because, on all these will depend the estimate of total service life. Units of service may be of more consequence than years of service in estimating service life.

Decretion may be due to age alone, as some properties grow old regardless of the use to which they are put. Sometimes this aging depends on the care given the properties. Wood decays, iron oxidizes, brick disintegrates, even stone is destroyed by the elements, some kinds more rapidly than others. The particular use to which these substances are put, whether in sheltered or exposed situations, may determine the rate of decretion, which for some uses may be practically or actually nil, within the range of human estimates. The effect of weathering often may be overcome by periodic repairs, and a given structure may remain in use for many years, and even perpetually, the structure of a given day having in it no item that was in it when it was first built. Such structures will always show some physical deterioration—the immediate or approaching need of some replacements or repairs.

Decretion may be due to immediate or approaching inadequacy. A given machine may be doing a work of constantly increasing magnitude which now or later will require a larger machine before the present one is worn out. The present machine may be good for a considerable service within its capacity. It may have, therefore, a large salvage value, but, for the purpose for which it is being used, it is approaching the end of its service life.

Decretion may be due to obsolescence. A machine may belong to a class that is more or less rapidly changing patterns and forms, due to an advancing art or science. Long before it is worn out, new forms may have been devised which are so much more efficient that it may no longer pay to keep the old machine in service. Or advancing civilization, growth of population, and changing character of social life may call for a different service from that rendered with satisfaction to the people served under the old conditions. This sort of decretion is not due to inadequacy, but to obsolescence.

The several causes mentioned may exist singly or together in a given plant, or plant unit.

Decretion of a plant unit may also be caused by accident.

Decretion always Present in a Going Property.—Decretion is likely to exist in almost every physical item of a going property except land. Even the Pyramids are slowly passing away, and, between items of very long life and those, like working tools, of very short life, there are all degrees of length of service life. Some properties, like water-works or gas properties, are essentially all new when they begin to operate, because, though some pipes may have been in the ground for some time, their total service life is so long that this preliminary exposure to decay may be neglected. Shortly after a water or gas property begins to operate, its machinery and structures have begun to deteriorate, and could not be inventoried as new, even for the purpose for which they are used, although they may be giving just as efficient service as new machinery and structures could give. Other properties, like railroads, have some items that are essentially old when regular service begins. Ties, for instance, begin to decay with some rapidity as soon as they are laid in the track, and often by the time a newly created extensive property has reached the operating stage they are being replaced almost or quite at the usual normal rate on the older part of the road.

Due to these facts, no going property could ever be inventoried as new if taken item by item or unit by unit, because some of the service life of practically every item or unit will have passed. As a result of this fact it can be shown that when the properly weighted average of all the decretion of the various units of a well-maintained railroad, for instance, is found, the railroad property as a whole cannot show more than from 80 to 90% of new condition, or there is estimated, say, 15% loss of value due to decretion of various units.

The Troublesome Problem.—Although, in a well-maintained property, decretion is always present in some degree, yet in some cases this decretion, converted into loss of value, should not be considered to be a deductible quantity in finding the value of the property—that is, it should not be considered as depreciation of valuation, or fair depreciation. Unfortunately, this has not been entirely understood.

Whether or not, and to what extent, if any, the loss of value due to existing decretion shall be deducted from original cost to date or cost of reproduction new, when finding fair value for any purpose, is the great troublesome problem of depreciation in valuation. This problem will be discussed after explaining accounting depreciation.

Accounting Depreciation.

General Statement.—To understand accounting depreciation, as defined in the Glossary, it is necessary to know something of the fundamentals of methods of accounting for depreciation. Bringing

depreciation into the accounts of a company owner is one of the steps necessary to keep the earnings and property statements correct.

Many owners have not understood, and some do not now understand, the necessity for charging off depreciation as it accrues. Sooner or later, such owners are brought face to face with the necessity of renewing plant units with no means available, because profits have been over-estimated and a part of the capital has been distributed in the past by reason of the failure to account, as it progressed, for depreciation, which though not apparent, was nevertheless accruing.

Moreover, with respect to public service properties likely at some time to be valued for purchase, or the settlement of some rate or other public question by a regulating body, or a Court, the owner may find the Knoxville decision troublesome, tending to prevent a finding of the real value of his property, if he has not been careful to account for depreciation as it has accrued.

There are various methods of accounting for depreciation. In many cases the method is prescribed by a public regulating body. When it is not thus prescribed, the method applicable to any given property may depend on the law, or, with different methods conforming to the law, on fairness or convenience. What is fair or convenient may depend in part on the character of the property to be accounted for, whether made up of long- or short-lived items, whether stationary, growing rapidly or slowly. The method to be adopted for a given property should accord with a reasonable interpretation of law, and sound business principles.

Fundamental Principles.—

1.—The owner of a public utility is under obligation to the investors in its securities to maintain the integrity of the investment.

2.—The public is under obligation to the utility owner to pay a fair price for the service rendered and to meet fairly its other contractual obligations fairly. Of concern in the present discussion is the obligation to include, in the fair price for service, an allowance for the maintenance of the integrity of the investment; that is, an allowance to cover the gradual destruction or deterioration, including estimated inadequacy and obsolescence, of the physical property as this occurs. This means that when, for any ordinary reason, an item of physical property is retired, a sum equal to its cost, or some equivalent of this sum, paid by the people who have been served, should be in the hands of the company owner to make good the loss due to the retirement of the item.

It is immaterial to the maintenance of the service how this is paid by the people, whether in a lump sum when the item goes out of service, or a little at a time, more or less in proportion to the gradually lessening service life of the item; but law or convenience may dictate the

manner of payment. As a matter of convenience, and of fairness to the using public and the owner, those methods of payment should be adopted which, conforming to law, avoid great irregularities in operating expense, in dividends, or in rates for service—that is to say:

3.—The return to the investor and the rates to the consumer should be kept reasonably stable and uniform from year to year, and should be fair.

The respective obligations of the public and the corporation are set forth in numerous Court decisions; the obligations of the utility to the investors in its securities are plainly stated in the Knoxville case.

Classification of Property Units.—Simplicity of accounting requires the use of different methods for different property units. It will be plain, perhaps, that the cost of such property as fuel, oil, waste, and supplies in general, which one can see are consumed in quantity from day to day and from hour to hour, do not represent investment, as the term is generally used, but operating expense; and such property used during any fiscal period should be paid for by the public during that period. The usual fiscal period is a year, and it may be said fairly that the cost of any property used up during a year is properly a part of operating expense.

This reasoning would apply also to parts of units, such as tubes of boilers, tires on locomotive driving wheels, shingles on buildings, etc., the replacement of which, though not occurring annually, may be classed as repairs rather than as renewals. The units are not retired, they are only repaired. All replacements that properly may be called repairs may without question be provided for in operating expense.

Closely allied to fuel and other supplies, but really representing investment, are certain other classes of property, like telegraph poles, railroad ties, etc. These last for a number of years, but not all of any kind last the same number of years, and a condition gradually comes about, in a stationary or slowly growing property, that calls for a renewal of a certain fairly regular percentage of all the poles or all the ties each year. The maintenance of the normal condition of poles or ties, which condition is necessarily less than new, properly may be charged in operating expense. The depreciation actually accruing during any year is offset approximately by equivalent expenditures for renewals. Simplicity of accounting does not "require" this method of handling tie accounts, but they have nevertheless been handled in this way. The integrity of the original investment, if that is measured by the service life of physical items, is not maintained by this method, because initial depreciation is not made good.

The difference between normal condition and condition new, of such items as have been mentioned above, may be called initial decretion, producing what is sometimes estimated as depreciation. Ap-

parently, under a strict interpretation of the law, such initial depreciation must be lost to the owner in a valuation unless:

1.—He has collected an adequate allowance for depreciation from the beginning; or
2.—The whole thing is ignored as not reducing the value of the property as a going concern; or
3.—It is considered that this depreciation is a development cost which, added to the other costs, will offset itself when full depreciation is estimated.

Forming a link between such property, as ties and poles and the next distinct class to be mentioned below, is such property as the rolling stock of a great railroad. The items are much larger than the separate ties, but the aggregate yearly expenditures for renewals may be not more than those for ties, and in the past the cost of renewals has been put into operating expense as the renewals occurred, under the head of repairs and renewals; but it may be met just as well by moneys taken from a fund, maintained by sufficient annual contributions for depreciation from the patrons of the utility, or by new capital furnished by the owner in lieu of that contributed by the patrons as depreciation allowances, but invested otherwise in the property by the owner. The Interstate Commerce Commission now requires that reserves be set up for the rolling stock of railroads, but, with respect to initial depreciation existing before such reserves were established, when retirements were handled as operating expense, the owners are situated exactly as they are with respect to ties, and they must lose such depreciation in a valuation unless the commissions or Courts will accept in their favor one of the two alternatives last mentioned in the foregoing paragraph.

Theoretically, the public contributes only the cost of the items retired. The items purchased in place of these may cost more or less than the items retired. Only the cost of the items retired should be charged against the depreciation contributions, and this should be charged, whether or not a new item is purchased.

The depreciation of certain other property units, as the very large and costly structures of a great railroad, the cast-iron pipe lines, or the pumping engines of a water-works property, the buildings, pipe lines, and holders of a gas property, etc., all having long life, and some of them involving, for the maintenance of the service rendered, relatively large expenditures at irregular intervals, can be provided for best without question by regular annual allowances established for the purpose, and accruing from year to year for each item somewhat in proportion to the spent life of the item. If proper accounting is provided, it is immaterial, except as a matter of public policy and economy, whether the allowances for any particular item be held as

cash at interest or as convertible securities until that item is retired, or be invested in additions or betterments to the property. In either case the integrity of the investment is maintained.

The Replacement Method.—The replacement method is an accounting method which provides that the owner shall be reimbursed for the cost of a property unit at the time it reaches the end of its service life and is retired. That is, the cost is charged to operating expense at that time. Operating expense being collected from the public, it is said that the owner is reimbursed when the charge to operating expense is made. Some owners do not charge the cost of the retired item, but rather the cost of the item which replaces it—if such there be—which may be more or less than the cost of the item retired. If it is more, the public is contributing capital to this extent; if less, the owner is losing capital to this extent. This practice is prohibited by the Interstate Commerce Commission for large telephone companies, although permitted for many classes of railroad property.

The replacement method is the most convenient one to use for some short-lived property units, but, under a possible interpretation of the law as laid down in the Knoxville case and the Minnesota rate cases, the method is not strictly applicable to any wasting property units, because it seems not to keep the investment intact at all times. However, the method should be legally proper for railroad use for all units except equipment, because the regulating body, the Interstate Commerce Commission, has sanctioned it, and the Committee believes that a proper interpretation of the Knoxville decision would also permit the use of the method in some other cases, certainly to the extent that replacements may be properly classed as current repairs. For the language is to the effect that the public utility "is entitled to see that from earnings the value of the property invested is kept unimpaired," and that: "before coming to the question of profit at all, the company is entitled to earn a sufficient sum annually to provide not only for current repairs, but for making good the depreciation and replacing of parts of the property when they come to the end of their life."

To explain the method more fully, let railroad ties be considered: They are an elementary part of the unit known as track, and, in estimating cost, would be an item in the inventory. If an old track is properly maintained, about the same percentage of the ties will be replaced with new ones each year—ties will not all disappear and be replaced at once. In the beginning they were all new, though, in the case of a railroad of magnitude built in one operation, some of the ties first laid will have reached nearly the ends of their lives by the time the whole line is completed. What will come about with such a road will be a condition such that at any given time there will be some ties ready to be replaced, some new ties that have just been put in, and perhaps approximately equal numbers in all stages of

life, so that the whole would inventory about 50% of new condition. Ties never can be much better than this nor much worse in an old, well-maintained track. In northern latitudes they may be a little under normal in the spring, just before renewals begin and a little above normal by the end of the summer, when renewals for the season have been completed. Ties in such track are kept in normal condition with respect to investment and service if they are kept in about 50% condition by annual renewals accounted for in operating expense. This is not exactly true when there is much recently added new track, but relatively small additions do not greatly disturb the balance.

When property is maintained in this way it is said to be maintained under the replacement method of accounting; theoretically, the cost of the old item is charged off, that is, credited to capital and charged to operating expense, and the cost of the new item is charged to capital when the replacement is made, and no accumulating depreciation allowances are provided or needed. Really, no entry need be made in the capital account unless the new item is cheaper or more costly than the old, and, in the matter of ties, is not made usually in any event, ties being considered much like fuel.

It has frequently been insisted that allowances for depreciation are strictly for the purpose of making replacements, and from this point of view property units retired without being replaced would not be provided for by the replacement method, but, in modern accounting, a unit which is retired and not replaced is, and in equity should be, treated in the same way as if it were replaced. That is, its cost should be made good to the owner, and is made good by charging it to operating expense.

Before describing other methods of accounting, an effort will be made to distinguish between depreciation reserve and depreciation funds, and to state the depreciation theories on which accounting methods are based.

Depreciation Reserve vs. Depreciation Fund.—Depreciation reserve and depreciation fund are two entirely distinct and separate things which are frequently confused, largely because of the loose terminology used in the past by accountants, valuation engineers, Courts, and commissions, all of whom have used the terms interchangeably, and have sometimes increased the confusion by speaking of either as the "depreciation reserve fund." The depreciation reserve represents merely the result of a series of entries on the books, made for the purpose of preventing overstatement of earnings or property, as will be explained later; but a fund is money or its equivalent set aside to be devoted to some particular purpose, a depreciation fund being set aside to provide for depreciation of property.

On the balance sheet of any enterprise, various items of assets appear, and among these will be the value of the property. If this property is carried at its full original value or cost on the asset side,

but has been in service some time and has lost some of its value, this fact should appear on the balance sheet in some way, or the actual value of the property on any given date will be over-stated by the amount of the depreciation. Hence, in modern bookkeeping the item of depreciation reserve appears on the liability side of the balance sheet, which makes the property showing, at least so far as the effect of depreciation is concerned, correct, provided the depreciation has been properly estimated. This same result could be achieved by simply writing off a certain part of the value of the property, carrying the property on the asset side at its depreciated or written-off value and making no entry on the liability side of the balance sheet. This, however, is not considered to be as valuable a method from an historical standpoint as that which carries property at its full value on the asset side and sets up a reserve on the liability side of the balance sheet to allow for the depreciation.

When a depreciation reserve is established for the balance sheet, one or more depreciation reserve accounts are carried in the ledger. As illustrating the use of the depreciation reserve accounts, let it be supposed that a certain item of property has depreciated $100 during a given year, and that no cash has been expended for it, nor is any expenditure to be made immediately. Although no expenditure is to be made immediately, or has been made, the fact of the depreciation means the consumption of $100 of invested capital, and, unless an entry is made to show this, the net revenue for the year will be overstated. Therefore, although no cash is spent, the operating expense account is charged with $100; but, operating expense being charged with $100 which is not spent, a surplusage of cash or its equivalent to the amount of $100 will be found. To offset this and prevent the overstatement of the assets, the depreciation reserve account will be credited with $100. As time goes on, the item will continue to depreciate, and the depreciation will be charged periodically in operating expense and credited to the reserve account, until finally the item will be retired. At this time, assuming that it has no salvage value, it will be written off from the property statement on the asset side of the balance sheet, and at the same time its value must be taken from the reserve in order still to preserve proper balance. Therefore, the reserve will be charged with the whole value of the item, which, if the estimates of depreciation from time to time have been correct, will be just equivalent to the sum of the credits to depreciation reserve for this item.

Whenever a charge is made against operating expenses for depreciation, the depreciation reserve account is credited. When property is retired, the cost new less salvage recovered is charged against the depreciation reserve. At any given date, therefore, the amount that should appear in the depreciation reserve on the balance sheet would be a summary of the credit balances of the various depreciation reserve accounts appearing in the ledger. If the estimates made for

depreciation from time to time happen to agree with the fact, the amount standing in the depreciation reserve item on the balance sheet at any time will represent the accrued depreciation in the property, but this is likely seldom to be the case.

The depreciation reserve exists in modern bookkeeping, whether or not there is a depreciation fund. The depreciation fund is a part of the assets, and is established merely by charging the fund and crediting cash or some other asset item with any amount that at any time may be deemed proper. This double operation does not disturb or change the amount of the assets, but merely changes the names under which they are carried.

It should be borne in mind that the setting aside of assets in a depreciation fund is not charging depreciation. This is accomplished only by making a charge against operating expenses and so decreasing the showing of net earnings. Depreciation is not provided for until it is charged in operating expense, and it is not deducted from the property until it is credited to depreciation reserve, or written off from the property statement on the asset side.

Practically, of course, collection may be made from the public without any depreciation entry in the books, that is, enough may be collected in rates to pay operating expense, depreciation, and fair return, but that part which should be applied to the property to cover depreciation may be otherwise disposed of, as, for instance, distributed as unwarranted dividends; and, when this is done wittingly, a theft has been committed from the property, and, when done unwittingly, error of management is shown. The argument in the foregoing paragraph assumes an honest and proper management.

Under the replacement method of accounting, there would be neither depreciation reserve nor depreciation fund, the reserve being established only when operating expense is charged without expenditure of cash, and under this method at any time the property will be over-stated by the amount of the depreciation accrued but not yet realized through retirements.

If no charge is made to operating expense or credit to reserve for depreciation of an item previous to its abandonment, but specific assets are set aside as a fund to offset the accruing depreciation of the item, "depreciation fund" will appear among the assets, but, as before, the profits and the property will be over-stated at any time by the amount of depreciation accrued but not realized by retirement.

Depreciation Theories.—Depreciation of physical units used in connection with public utilities, or, indeed, with any other industries, does not proceed in accordance with any mathematical law. One unit, identical with another, and used for the same purpose in the same way, goes out of service before the other, perhaps because of some accident; or a unit goes out of service before it is worn out,

because of some new invention that displaces it, or some new requirement of service that makes its use no longer possible; another unit, performing hard service, requires so much more repair during its later than during its earlier life, and yields so many fewer units of service per unit of time, that, long before it is actually worn out, it becomes uneconomical to use it, and it is replaced some time before it is incapable of service. There is no regularity in the development of the increasing need for repairs; there is no regularity in the progress of depreciation; but, in order to devise a reasonable plan for laying aside allowances from year to year to make good the depreciation as it accrues, and to provide for the accumulation of a sum equivalent to the cost less salvage of a unit by the time it is retired, some theory of depreciation progress must be assumed on which such allowances may be based. Several such theories have been suggested, and corresponding accounting methods have been developed for some of them and have been adopted by accountants and approved by Courts and commissions. Three of the more generally mentioned theories will be explained, namely: The straight-line theory, the compound-interest theory, and the unit-cost theory; and the corresponding accounting *methods* will then be discussed.

The Straight-Line Theory.—The straight-line theory assumes that depreciation progresses uniformly from the beginning of service to the end of service life; that when service life is half gone, value less salvage is half gone, when service life is nine-tenths gone, value less salvage is nine-tenths gone. Thus, if a unit cost $100 and has a salvage value of $10, after an estimated total service life of 10 years, and has been in service for 5 years, it has depreciated in value one-half of $90, or $45, and is worth $45 plus $10 salvage, or $55; if it has been in service 9 years, it has depreciated $81 and is worth only $19. This is the simplest depreciation theory, and because of its simplicity it has been widely adopted. Its application in accounting and valuation is sometimes attended with certain apparent inequities which will appear in the discussion of accounting under this theory.

The Compound-Interest Theory.—This theory assumes that depreciation progresses at the same rate as a sinking fund grows from an annuity accumulating at compound interest. Thus, if a unit cost $100 and has a salvage value of $10 after a total service life of 10 years, an annuity may be determined such that, with its accumulation of interest, it will equal $90 at the end of 10 years, and the depreciation of the unit at the end of any year will be equivalent to the accumulation of the annuity and its accretions to that time. If the rate of interest be r; the cost less salvage of a unit be C; and the estimated service life N years; the annuity necessary to set aside to equal C in N years is given by

$$A = \frac{C\,r}{(1+r)^N - 1} \qquad (1)$$

and the sum to which this will amount in n years is given by

$$S = \frac{C[(1+r)^n - 1]}{(1+r)^N - 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

This may be solved by logarithms, or the result may be taken from amortization tables, many of which have been published covering Equations (1) and (2). In applying these equations to a particular example, let it be assumed as before that a service unit costs $100, has a salvage value of $10 after a total service life of 10 years; that it has served 5 years, and that interest is at the rate of 5 per cent. Then $90 must be accumulated in 10 years, and the necessary annuity, A, at 5% is $7.16. This annuity, with its accumulation of interest, will amount to $39.54 in 5 years, and the unit is then worth $50.46 plus $10.00 salvage, or $60.46. After 9 years of service, the depreciation amounts to $78.90, and the unit is worth $11.10 plus $10.00 salvage, or $21.10. The depreciation during any one year is equivalent to the annuity for that year plus the interest on the accumulation of previous annuities and interest.

This theory may have a certain practical advantage over the straight-line theory when applied to newly created properties, because it requires the setting aside of a less sum to offset accruing depreciation in the earlier years of the enterprise, when expense is likely to be relatively high and income relatively low. On the other hand, when applied to a unit for which the cost for repairs and upkeep is much greater toward the end of its life than at the beginning, this theory bunches the larger deductions from income for repairs and depreciation; and the straight-line theory would tend to produce less inequality in the deductions throughout the years of service life, so far as this influence is concerned.

With some units, such as locomotives, the expense for repairs is so large that the depreciation deduction is relatively insignificant and, so far as inequality of deductions is concerned, it is of less consequence which theory is adopted than it is when units like water pipe are under consideration, because the item of repairs on such units is relatively insignificant when compared with the accruing depreciation.

The discrepancy between accrued depreciation under the straight-line theory and under the compound-interest theory is much greater when the units are long-lived than when they are short-lived. Thus, a 10-year unit having no salvage value loses half its value in 5 years under the straight-line theory, regardless of the rate of interest, and at 5% under the compound-interest theory it loses nearly as much—about 44% of its value in the same time (45.1% at 4% and 41.6% at 7%); but a 50-year unit, losing half of its value in 25 years, under the straight-line theory, loses only 22.8% of its value at 5% under the

compound-interest theory. It will be shown later, however, that the total cost for service during the service life of a property unit, including interest on the value in the unit, depreciation annuity or allowance, and interest on both these annual costs, is exactly the same under one theory as under the other, and indeed is the same as under the replacement method of maintaining property already described, but, notwithstanding this equality, the theories are not equally applicable to all classes of property, as will also be shown later.

The Unit-Cost Theory.—This theory holds that the depreciation of a service unit at any stage of the service life is the difference between what it cost new and what could be paid for it in its depreciated condition without increasing or diminishing the cost per unit of service during its remaining service life. In other words, it is equivalent to the difference in worth of two units which would perform the same service at the same total cost per unit of service, one having an estimated service life equal to the total estimated service life of the unit under consideration, and the other an estimated service life equal to the estimated remaining service life of the unit. Comparing the relative economy of two such units in general, the engineer solves a question like this: If Unit A costs \$100 and lasts 20 years, how much can be paid with equal economy for Unit B for the same service, if it will last but 10 years? The costs must include all costs necessary to put the units in place and at work. The estimate should include consideration of the effect of the lessened output of service and greater cost for operation and repair of the units, as they draw near the ends of their lives; but this effect is sometimes ignored. When excluded, the "unit-cost theory" becomes the "compound-interest theory", which, therefore, may be considered to be a special case of the "unit-cost theory". On the basis of this theory of difference in worth, considering Unit A as the unit new and Unit B as the depreciated unit, a formula for the present worth of the depreciated unit is developed thus, ignoring output and cost of operation and repairs: The two units are compared on the basis of equal annual cost for interest and depreciation annuity. If C be the cost new of Unit A and c the present worth of the depreciated unit, B; r the rate of interest; N the estimated service life of A; and n the estimated service life of B; the total annual costs for interest and annuity will be:

$$\text{For } A \ldots \text{Interest, } C\,r, \ldots \text{Annuity, } \frac{C\,r}{(1+r)^N - 1}$$

$$\text{For } B \ldots \text{Interest, } c\,r, \ldots \text{Annuity, } \frac{c\,r}{(1+r)^n - 1}$$

Making these two equal and solving for c gives

$$c = C\,(1+r)^{N-n}\,\frac{[(1+r)^n - 1]}{[(1+r)^N - 1]}$$

and $C - c$ would be the depreciation during $N - n$ years, which will be found to be identical with the S of Equation (2), if $(N - n)$ be substituted for n in that equation. This is the compound-interest theory.

If the items of increased cost of operation and repairs be included, the application of the unit-cost theory becomes quite complex. The comparison is made in the same way by making total annual costs equivalent, but the annual cost is first reduced to cost per unit of service by dividing by the estimated output capacity of the new and depreciated property units. Thus, if A and a are costs of operation and repairs for the longer- and shorter-lived units (new and depreciated units), respectively; C and c the respective costs, C being the actual or estimated cost of the new unit of longer life and c the price that could be paid for the shorter-lived (depreciated) unit to produce the same cost per unit of service; B and b the respective depreciation annuity multipliers of C and c under the sinking-fund theory; if D units of service may be realized annually from the longer-lived (new) unit and d units from the shorter-lived (depreciated) unit; and if r be the rate of interest, the following equations of annual costs may be written:

$$\frac{A + B\,C + r\,C}{D} = \frac{a + b\,c + r\,c}{d}$$

Solving this equation for c, the price that could be paid for the shorter-lived (depreciated) unit is found to be:

$$c = \frac{\frac{d}{D}(A + B\,C + r\,C) - a}{b + r}$$

The difference between C and c is the accrued depreciation at the date of estimate. The amounts of B and b may be obtained from

$$B = \frac{r}{(1 + r)^N - 1}$$

and

$$b = \frac{r}{(1 + r)^n - 1}$$

or from amortization tables. The capacities, D and d, of the new and old units should be their actual or estimated capacities for service under normal conditions, not the respective outputs under varying business conditions which might readily make the older unit more valuable than the newer one.

The compound-interest theory produces, in its application in accounting, equal annual charges for the sum of interest and depreciation allowances, while the unit-cost theory is based upon equal

annual charges for the sum of interest, depreciation allowance, and operating expense (including repairs) *per unit of output.* This theory is probably the soundest theory of depreciation, and, when applied with intelligence, probably furnishes the truest measure of accrued depreciation. It is not readily applicable to accounting purposes, because its formulas cannot be tabulated, but it may be used for the purpose of checking the results of the application of other theories and for finding the accrued depreciation of any property at any time, in connection with a public valuation, when there has been no proper accounting in the past, or for finding remaining value for the purpose of inaugurating a proper accounting system for an old property.

Methods of Accounting Applicable to the Straight-Line and Compound-Interest Theories of Depreciation.

This discussion will be approached from the standpoint of the proper payments of the public to company owners and the proper disposition of these payments by the company owners, rather than from the standpoint of the bookkeeping methods of the company owners. It should be remembered here that it is the duty of the public served to pay operating expense incurred in its service, interest on capital invested for its service, and the cost of property consumed in its service; but operating expense is omitted from this discussion as being independent of the other two items, which are to some extent mutually dependent on each other, and because it is only depreciation accounting that is now under consideration.

Accounting Under the Straight-Line Theory.—Under this theory the public will pay the full amount of the depreciation as it accrues, a certain uniform fraction of the whole cost, less salvage value, of any unit each year of its life, and, paying this each year, thus returning a part of the invested capital, it should pay a correspondingly decreased interest on invested capital each succeeding year. A tabular statement of a particular example will illustrate: A certain unit costs $100, has a life of 20 years, and no salvage value. The cost or book value in the unit and the payments of the public with interest at 5% are shown in Table 1.

Remembering that the property must be considered to be a continuing property and that the company owner is bound to preserve the integrity of the investment, it must be clear that the allowances paid by the rate-payers belong to the property and must be considered to be a part of it. If taken out of the property, the investment is impaired, and if paid to the stockholders, then, although they lose nothing, the bondholders' security is reduced, and the public and later stock purchasers are not protected against the gradual destruction

of the property that should be a continuing property. Practically, therefore, the depreciation allowances paid by the rate-payers must be considered a part of the property, not to be distributed to the stockholders, but to be kept in the property in some form, in order to preserve the integrity of the investment.

TABLE 1.—ILLUSTRATION OF THE STRAIGHT-LINE METHOD.

Showing Book Value and Payments by the Public on Account of Fair Return and Depreciation.

Property Unit Costing $100.00, Lasting 20 Years, No Salvage Value, Interest at 5 Per Cent.

(1) Age.	(2) Remaining value at end of year.	(3) Depreciation allowance.	(4) Return on remaining value, 5%.	(5) Combined depreciation and return, 5%.

Totals.....		$100.00	$52.50	$152.50

The allowances, being part of the property, ought to earn at the same rate as the capital remaining in the property. That is, persons having invested in a given property do not wish the investment continually to vary either in amount or return rate, they desire that the investment shall remain and shall earn at a uniform rate. The allowances may be made to earn at the same rate as the remaining property, if reinvested immediately in the property; they may earn at an even greater rate, if fortunately invested otherwise; or they may and probably will earn at a less rate, if placed in bank. Immediate investment in the property itself, which should insure a continuance of the full rate of return, may not be possible, often will not be when a property is not rapidly growing, and lack of opportunity for other investment may require the banking of allowances. It would seem, therefore, that the public should make up the shortage in return, if any there be. Theoretically then, proper accounting, under regulation that determines fair return by which full return on the entire investment is secured, would charge to operating expense any deficiency of return on allowances and credit to income any excess of return over the fair rate.

When only a single item is considered, this method, as the table shows, makes payments from year to year ununiform, with much larger payments in the beginning than toward the end, which is undesirable unless repairs are enough greater toward the end to equalize the payments. When there are many items of varying ages and expectations of life, this defect largely vanishes. This is not a defect of the accounting, but a necessary result of using the straight-line theory of depreciation.

Accounting Under the Compound-Interest Theory.—Under this theory, the public pays interest on the invested capital and depreciation as it accrues, according to the compound-interest theory, but there are different ways of considering these payments and distributing them in the accounting, leading to two or more different methods of accounting. The Committee will discuss two methods, namely: 1, the compound-interest method, heretofore called the equal-annual-payment method, and 2, the sinking-fund method.

1. *The Compound-Interest Method.*—Confining the discussion to a single unit without salvage value, for simplicity, the amount of the annual payment for interest and depreciation is found thus: If C be the cost of the unit; N the years of service life; r the rate of interest for fair return; and r' the rate to be used in amortizing the property; the total annual payment, P, by the public for fair return and depreciation is given by

$$P = Cr + \frac{Cr'}{(1+r')^N - 1}$$

the second term being evaluated by logarithms or taken from amortization tables. It will perhaps be plain that this should be the payment for the first year, but for the second year the payment should include interest on the amortization annuity of the first year, if the public served is to pay the full depreciation as it accrues, and the return should be on the original cost reduced by the first annuity, just as in the straight-line method. For the third year, the cost, or value, should be reduced by the depreciation payments of the first two years, and the depreciation payment should include interest on the sum of the two preceding depreciation payments, and so on. Now it may be shown that if r' equals r, all these several annual total payments for interest and depreciation are identical in amount and equal to that first above written for the first year. If r' does not equal r, the total payments are not the same throughout the years. Table 2 will show the remaining value, depreciation accruing, and total payments on account of fair return and depreciation, when the amortization interest rate is assumed the same as the fair rate of return—5%, and when the latter is the larger—7 per cent.

This method of disposing of the payments of the public on account of fair return and depreciation was called, in the Progress Report, the equal-annual-payment method, because it seemed to make the total payments on account of operation, return, and depreciation more nearly equal from year to year than other methods that had been discussed. As it does not necessarily do this in all cases, it might better be distinguished from other methods by a more exact title. Under this method the total payment of the public served, for interest and depreciation, is divided into two parts, one the full annually accruing depreciation under the compound-interest theory, and the other, return on the depreciated cost of the unit. This is exactly analogous to the straight-line accounting method, the only difference being in the amount of the accruing depreciation. It is the complete and logical method of accounting for the payments of the public for interest and depreciation under the compound-interest theory of depreciation, and the method will be given the name of the theory and will be called the "compound-interest method", logically comparable with the use of the "straight-line method" under the "straight-line theory". Although the name "equal-annual-payment" has gotten into valuation and accounting literature, this literature is in a transition stage, and the Committee thinks there is good reason in the preceding argument for the new name.

2. *The Sinking-Fund Method.*—Sinking fund is a very old term and has long been connected with the plan of providing for the payment of a debt, which is to become due in the future, by setting aside and investing a properly determined annuity, such that, with accumula-

TABLE 2.—ILLUSTRATION OF COMPOUND-INTEREST (EQUAL-ANNUAL-PAYMENT) METHOD OF ACCOUNTING FOR DEPRECIATION.

tions of interest, the amount of the funds in hand when the debt matures, will be equal to the amount of the debt. Only in comparatively recent years has the method been used for the amortization of wasting properties. It is not so well adapted to this purpose, as to

the amortization of a debt, particularly when the property is a public utility. The method contemplates the creation and maintenance of a fund which, considering the danger that it may be misapplied, is against good public policy. Moreover, when a property is growing it is good economy to use the annuities in extensions of the property; but there is danger, when this is done, that confusion in the accounting will result, and there is always danger that some persons may confuse annuities without their accretions, with the depreciation that the annuities plus their accumulations of interest are intended to cover. Under this method, the public served is credited with paying only the annuity toward depreciation, its payments on this account, therefore, being equal from year to year. The remainder of the total payment for interest and depreciation is treated as fair return computed on the undepreciated cost of the unit concerned. As this is also always the same, the total payments of the public for fair return and depreciation are always the same throughout the years, and the amount is that above written,

$$P = C\,r + \frac{C\,r'}{(1+r')^N - 1}$$

If r' equals r, the total annual payments agree in amount with those of the compound-interest method, but, if the return rate is higher than the amortization rate, as has been usual in practice heretofore, the total annual payments by the sinking-fund method are larger in the later years than those of the compound-interest method as shown in Column (7) of Table 2, and thus the company owner is overpaid. It has already been argued that the same rate of return should be earned by all capital kept in or held for the property, and hence it should be true that amortization rates of interest should be the same as fair return rates, and they will be so considered in the remaining discussion. Thus, the total annual payments by both methods will be identical. As full payment for interest and depreciation is made under the compound-interest method and the same totals are paid under the sinking-fund method, full payment must be made under this method.

To defend crediting the public with only the annuities toward depreciation and full return on the undiminished cost of service units, one of two arguments is invoked:

1.—The annuities are paid to the company before it has occasion to use them to retire the units they are intended to cover; hence, the company owner can earn interest on them, and therefore they are discounted and considered parts of a fund held in trust by the company owner and invested for the purpose of earning that interest necessary to make it amount to the payment required of the public when the unit covered is retired. As the company may not earn distributable profits

on these annuities, it must be allowed its fair return on the undiminished cost of the units covered until such time as the fund matures, which in theory should be when the item is retired. If the fund is then immediately reinvested in the property, the cost value goes on as before; if, for any reason, it is withdrawn from the property, the cost value should be reduced accordingly.

2.—The public is assumed to make full payment on account of depreciation yearly as it accrues; but, because it makes these payments in advance of the time when they must be used to retire the unit they cover, the company owner will be able to use them to earn interest, and hence the public charges the company for the use of these payments assumed to be due only when the item is retired; that is, the public pays the present worth of payments assumed to be due on the retirement of the unit covered. But, again, the company owner must invest these annuities so that with their earnings they shall equal the cost of the unit covered when it is retired; they cannot be used to earn distributable profits, and, therefore, as before, the public should pay a fair return on the undiminished cost value of the units concerned until they are retired or the payments mature. Under this conception, it must be assumed, either that the last payment due is made first and discounted, or that the growth of depreciation is reversed, the larger annual growth being at the beginning and the smaller at the end of service life. The conception seems not to be defensible.

Comparisons.—The entries to be made in the accounting under the compound-interest and sinking-fund methods must of necessity be different. Under the compound-interest method, the book value of the service unit must be reduced from year to year in the amount of the full accruing depreciation by a credit to depreciation reserve; under the sinking-fund method, the public paying return on the undiminished cost, there should be no deduction from book value until the unit is retired or the sinking fund matures, which times are theoretically the same. Thus, the sinking-fund method becomes, so far as the property account is concerned, the same as the replacement method of maintaining property. Unfortunately, this has not been understood clearly, and the sinking-fund method of accounting has not proceeded under this theory; confusion has resulted, and, indeed, is likely to result, from any attempt to account for depreciation under this method.

The Entries Under the Compound-Interest Method are, and are explained, as follows: Income in the amount of the depreciation allowance is charged to operating expense to keep the income statement correct. Depreciation reserve is credited in the same amount to keep the property statement correct. We now have assets consisting of property depreciated by the depreciation reserve and cash or other assets equivalent to that allowance. The depreciated property will earn

fair return the next year, and the allowance also should earn fair return. It may be—and should be, if possible—at once re-invested in the property, but, however it is used, unless retained as working capital, cash will be credited and the particular asset purchased will be charged, thus making no change in the total assets. If the allowance is invested in the property, fair return presumably will be earned. If this is not immediately possible, so that the allowance must be held for a time until needed in the property, it should be invested in outside securities, and the deficiency of fair return, if any, should be charged next year in operating expense, and the excess above fair return, if any, should be credited to income, reducing the necessary payment of the public on account of depreciation. Only on such an assumption is it fair to use fair rate of return in computing annuities. If the company owner must take his chances of earning more or less than the fair rate of return on the annuities, then that rate should be used which experience shows to be probably obtainable. In the case of a reasonably growing property, investment in the property will usually be possible though perhaps not immediate; in the case of a stationary property, it will in general be impossible.

There is no ambiguity in the foregoing described method; no chance for confusion; the method is exactly analogous to that described under the straight-line theory of depreciation.

The Entries Under the Sinking-Fund Method should be, and are explained, as follows:

Operating income, in the amount of the annuity, is charged to operating expense in order to keep the operating income account correct. As fair return is based on book value, there must be no reduction in this below original value, except as units are retired, so there will be no credit to depreciation reserve, which will reduce book value, but to some other liability account as trust fund reserve. Among the assets, cash or other assets will be credited, and sinking fund charged with the amount of the depreciation annuity. The fund will be credited only as cash is expended for the replacement of, or in lieu of, units covered by the fund. The fund must be carried as an undistributable asset belonging to and going with the property, to offset the trust fund reserve. Accounting must go on within the fund; its cash must be invested and its income accounted for separately from the operating income. If its cash is reinvested in the property itself, purchasing new units and increasing the income producing but depreciating property, the earnings from such new units should be charged to the fund. These units being depreciating units must also earn depreciation annuities, which must in turn be invested and in effect a new sinking fund must be set up for each addition to depreciating property. It would be manifestly impossible to separate the earnings of the several units of a complex property, but the operating income

can be separated into two parts, respectively proportioned to the investment from the fund and that from other capital, and its due share charged to the fund. This will be but an approximation to the truth and again it must be remembered that the additions are of depreciating property. Moreover, in a valuation it will be impossible to distinguish between units purchased from the fund and those acquired otherwise. If the fund is invested outside the property, no difficulty arises in determining the income. Theoretically, if it is invested so that it earns less than the rate assumed in determining the annuities (which, as has been pointed out, should be the fair rate of return), the deficiency may be put in operating expense and so collected from the public; and, if it earns more than the fair rate of return, the excess should be credited to the public sinking-fund reserve to the relief of the public. However the fund is invested, it must be held to be a part of the undistributable property, an asset to be included in a valuation offsetting trust fund reserve.

The foregoing procedure is more complex than that involved in the compound-interest method, and the sinking-fund method has no advantage over that method in any way. It does not show directly in the property account what the accrued depreciation is at any time, as does the compound-interest method, but presents the fiction—possibly justified by the existence of the trust fund reserve—of an undepreciated property. It must be remembered that the company owner has two elements of value in his property—money and time—that is to say, cost and length of service life, both of which must be protected. It is not enough that when a property unit goes out of service there shall be a new unit of equal cost to replace it, but the new unit must have a service life equal to that of the retired unit, or, there must be more units of less life, or less units of more life. Under a strict application of the sinking-fund method, when the fund is invested in the property, the foregoing result is realized only if the funds be set up for each separate addition, purchased with fund money, based upon the cost and service life of the addition. The intricacies of this method when strictly followed, the confusion likely to result when the fund is invested in additions to the property, and the desirability of such (latter) form of investment, seem to make this method of accounting, for depreciation of a growing property, undesirable.

The sinking-fund methods in common use in the past have varied from the foregoing procedure. Either annuity or full amount of accruing depreciation has been charged to operating expense, and credited to reserve, thus reducing book value. When only the annuity has been charged and credited, the property account shows depreciation, but not enough, and explanation must be forthcoming to justify the accounts and the distribution of public payments. The accounts

do not tell the whole story, as in the compound-interest method. If the full accruing depreciation is charged and credited, no sinking fund is required, and no explanation can justify any other distribution of the public payments than that of the compound-interest method which this procedure then becomes.

The sinking-fund methods heretofore generally used are incomplete accounting methods, under the compound-interest theory, in that outside explanation is required to justify the accounts and the distribution of public payments for return and depreciation. Since, as has been said before, there is full and complete payment by the public for return and depreciation under the compound-interest method, and since, with equal rates for return and annuity, the payments are the same in total amount under the sinking-fund method, they must be complete under both methods, and it would appear that the sinking-fund method so widely used must have been the outgrowth of a failure to comprehend the problem completely. At any rate, it seems no longer desirable.

Comparison of Four Methods.—

(*a*)—Compared to Bond Payments.—The four methods of accounting for depreciation may be compared to four ways of making and paying bonds. Thus, the replacement method corresponds to a bond payable n years from date, with interest at the rate of r per cent. per annum until paid; the straight-line method corresponds to a set of n serial bonds of equal amounts, with interest at the rate of r per cent. per annum, giving diminishing annual payments; the compound-interest method corresponds to a set of n serial bonds of unequal amounts, respectively equivalent to the annuity accumulations of the several years that the bonds run, giving equal annual payments. The sinking-fund method corresponds to bonds payable n years after date, and requiring a trust fund to be accumulated with a bank or trust company to meet the payments when due, also giving equal annual payments.

(*b*)—On a Basis of Costs.—To compare the four methods thus far described on a basis of cost, it will be assumed that the property is made up of a single unit, costing $100, having no salvage value, and lasting 20 years—of course, a purely hypothetical case. If interest for all purposes is at 5%, the annual and total payments by the public to the owners will be as in Table 3.

In preparing Table 3, the return under the replacement and sinking-fund methods has been figured as 5% on the undiminished cost of the property unit, while under the straight-line and compound-interest methods it has been based on the depreciated value of the unit.

The headings in Columns 9 and 10, while representing what is frequently considered to be "depreciation" and "return", are not expressive of the facts. The figures in Column 9 represent the sinking-fund annuity for each year, which is only a part of the depreciation, as may

be seen by reference to the total at the foot of the column, which is only $60.40 instead of $100. The remainder of the depreciation is incorporated in the figures in the column headed "Return", where in each year it represents 5% on the difference between the undiminished cost of the unit and its depreciated value in that year. Of the $100 represented by the total of this column, $39.60 is "depreciation" and $60.40 is "return".

Depreciation	100.00									
Total.	$200.00	$100.00	$52.50	$152.50	$100.00	$60.40	$160.40	$60.40	$100.00	$160.40

Although the total payments by the public for return and depreciation appear from the footings, under the various headings, to be different under the different theories, this apparent variation is the result of ignoring interest on the payments or, in other words, the effect of time.

The real total cost of the unit in the 20 years, for interest and depreciation, is the accumulation of the annual allowances for these items at compound interest during the 20 years, and this is the same for the four methods and is equivalent to the sum to which

the cost of the unit would amount at compound interest in the life time of the unit, as will be shown.

Referring to Table 3: by the replacement method, the total return of $5.00 each year may be considered as an annuity which at 5% in 20 years amounts to $165.33, to which must be added $100.00, the retiring payment, making $265.33. By the straight-line method, the payment for the first year is $10.00, which at compound interest for 19 years amounts to $14.57; the second payment is $9.75, which in 18 years amounts to $13.92; and so on, the total for the 20 years summing $265.33, as before. The payments by the two other methods are alike, $8.02, and these, treated as annuities, also amount to $265.33 in 20 years; but $100.00, the first cost of the unit, if placed at compound interest at 5% for 20 years, also amounts to $265.33. Thus is the statement of equal cost for the four methods and its equivalent shown for the particular case. It may be proved mathematically, as follows:

The sum to which any principal, P, will amount at r compound interest in n years is

$$S = P\,(1 + r)^n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The annuity F that must be set aside each year at r compound interest in order to realize P dollars in n years is

$$F = \frac{P\,r}{(1 + r)^n - 1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

and conversely the sum, P, to which an annual allowance at r compound interest will amount in n years is

$$P = \frac{F\,[(1 + r)^n - 1]}{r} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

The total cost of any unit in n years, being the amount of the total allowances for interest and depreciation at compound interest, if n be taken as the life of a unit costing P dollars, then:

By the replacement method, the annual payments are Pr for interest, and, at the end of the nth year, a gross sum of P dollars to make good the worn-out item. In the n years, the total cost will be the sum of the annual allowances of Pr dollars at compound interest plus P dollars. Therefore, using Equation (5), in which F becomes Pr, we have

$$\text{Total cost} = \frac{P\,r\,[(1 + r)^n - 1]}{r} + P = P\,(1 + r)^n \ldots . (6)$$

which by Equation (3) is the amount of P at compound interest for n years.

By the straight-line method, the annual contributions are not equal. They are for each year $\frac{P}{n}$ for depreciation, and a varying amount

for interest, as the depreciation is deducted from the principal. The series of payments for interest may be expressed as follows:

First year..... $P\,r$

Second year..... $\left(P - \frac{P}{n}\right) r$

Third year..... $\left(P - \frac{2\,P}{n}\right) r$

etc.,

nth year..... $\left(P - \frac{(n-1)\,P}{n}\right) r$

The total annual contribution then will be

First year..... $\frac{P}{n} + P\,r$

Second year..... $\frac{P}{n} + \left(P - \frac{P}{n}\right) r$

Third year..... $\frac{P}{n} + \left(P - \frac{2\,P}{n}\right) r$

etc.,

nth year..... $\frac{P}{n} + \left(P - \frac{(n-1)\,P}{n}\right) r$

Substituting those separate sums in a series of equations based on Equation (3) making the exponent of the parenthesis $n-1$ for the first equation, $n-2$ for the second, and $n-n=0$ for the last equation, there results:

For the first-year allowance.. $S = \left(\frac{P}{n} + Pr\right)(1+r)^{n-1}$

For the second-year allowance. $S = \left[\frac{P}{n} + \left(P - \frac{P}{n}\right) r\right](1+r)^{n-2}$

For the third-year allowance. $S = \left[\frac{P}{n} + \left(P - \frac{2\,P}{n}\right) r\right](1+r)^{n-3}$

etc.,

For the nth-year allowance..... $S = \frac{P}{n} + \left(P - \frac{(n-1)\,P}{n}\right) r$

and the sum of these several sums is $P\,(1+r)^n$, the same as given by Equation (3).

By the sinking-fund method, the annuity payment, Equation (4), is $\frac{Pr}{(1+r)^n - 1}$, and the total annual payment is this plus interest, Pr.

Hence the total cost in n years is the accumulation of these two items or, substituting, $\frac{Pr}{(1+r)^n - 1} + Pr$ for the F of Equation (5),

$$\text{Total cost} = Pr \frac{\left[\frac{1}{(1+r)^n - 1} + 1\right]\left[(1+r)^n - 1\right]}{r} = P(1+r)^n \ldots (7)$$

or the same as by the replacement method, and as Equation (3).

Since the compound-interest method involves exactly the same annual contributions as the sinking-fund method, the total cost must be the same, or, $P(1+r)^n$.

For the particular example assumed, namely, a $100.00 unit lasting 20 years, with interest at 5%, the total sacrifice for the 20 years, by any one of the methods, is

$$S = P(1+r)^n = \$100.00\ (1.05)^{20} = \$265.33.$$

(*c*)—With Respect to Legality and Safety.—The four methods showing identical costs, any one of them seeming to be most convenient may be chosen for a particular property or for a part of a property, provided only that it is legal, safe and fair, but the sinking-fund method, being incomplete within itself, is not recommended. The replacement method is open to the danger that a Court, valuing a property at any time, will charge against it whatever depreciation may be found, holding that depreciation of physical property is always loss of value of investment, and that, under the Knoxville decision, it must be deducted, whether or not, under accounting methods theretofore used, the depreciation had been collected from the public. Thus, the property would lose the accrued obligation of the public to pay for depreciation, which obligation must be considered an asset of the property in an equitable treatment of property maintained under the replacement method of accounting. When the method is ordered or authorized by a public regulating body, as has been done in the past by the Interstate Commerce Commission with respect to all railroad property, and is still approved for most classes of such property, it should be considered to be legal and should be safe, but not always has it been safe.

The straight-line and compound-interest methods plainly are safe, as they return the full amount of the depreciation presumably as it accrues.

The sinking-fund method perhaps requires interpretation to make clear when it is safe, as the public apparently does not return the full amount of the depreciation to the owner, and unless fully understood and properly applied by regulating or valuing bodies, it is not safe. Since the total annual payments for interest and depreciation by this method are exactly the same as by the compound-interest method, it must follow that if full payment is made in one case it is also made in the other, and that it is merely the bookkeeping distribution of these

payments which makes it appear that full payment is made in one case and not in the other. Under the sinking-fund method of accounting, the annuity assumed to be paid by the public, together with the interest on the accumulated allowances, must be charged each year to the fund held in trust for the property. The fund must be treated as a trust fund belonging to the property, or due from the public, and equivalent to physical property of equal value.

If for the purpose of public purchase or capitalization a valuation is made at any time of a property maintained under this method, depreciation will exist in amount equivalent to the accumulation of depreciation annuities and interest, if the various original estimates on which the annuities were figured have agreed with the facts as they have developed in the life of the property. To the depreciated value found will be added the accumulated allowances not invested in the property but treated as an asset due from the public and neither the company owner nor the public will lose anything, since 100% of original value will be found and the accounting may go on as before. If part of the fund is invested in additions and betterments, it will be difficult, if not impossible, to separate these from the original property, and they will be included ordinarily in the valuation; but the fund accounts should show what sums have been thus invested and what amounts remain in the fund as other assets. Only the portion of the fund not invested in the property can be added to the depreciated value. Again 100% of original value will be found to result, and purchase price will be so fixed, or the accounting may proceed as theretofore. The sinking-fund method, being likely to cause confusion and possible injustice, should not be used in depreciation accounting, but, if used, difficulties may be somewhat avoided if the fund is kept invested in assets wholly distinct from the property.

If a valuation is for the determination of fair return for the future, either of two courses is open: (1) The property may be listed at full value for the determination of interest, and full value and total service life for the determination of depreciation annuity; or, (2) The property may be listed at depreciated value for the determination of interest, and depreciated value and remaining service life for depreciation annuity. Either method is equitable, and both give the same total annual allowance. Thus, referring to Table 2, if a 20-year item costing $100.00 new has been in service 15 years, and interest is figured at 5%, the theoretical remaining value, under the compound-interest theory, is $34.74. The interest for the succeeding year is $1.73, and the depreciation annuity to retire the item in 5 years is $6.29, or a total of $8.02, which is just what is required to cover interest and annuity for the item considered new. A danger here—shown by experience to be real—is that the property will be listed at depreciated value for interest and full value and total service life for depreciation annuity.

Rate on Depreciation Allowances.—As having some bearing on accounting methods, the disposition of allowances, and the rate to be used for these allowances, the Committee desires to emphasize again the fact that the entire reasonable sum devoted to public service is entitled to a uniform fair return. While thus devoted, and while, as a matter of convenience or to conform to law, allowances for depreciation may be returned to the company owner approximately as the depreciation goes on, thus theoretically reducing the capital in the service, yet the obligation of the owner to keep the investment in the property intact, makes it improper for him to consider these allowances other than as a part of the property not to be distributed as income, or returned to his pocket, without corresponding reduction of capital, if not needed for the maintenance of the property. Therefore, he is entitled to a full fair return on the undiminished investment so long as its value is properly maintained in accordance with law. Hence the allowances returned to the investor to cover accruing depreciations should earn the same fair return as the value remaining in the property. To accomplish this these allowances are best invested in the property, but, when this is not possible, the amounts not thus invested should be placed in a fund sacred to the property, and the earnings of this fund should be accounted for—if less than a fair rate of return, the deficiency should be charged in operating expense; if more, the excess should be credited to income. Thus only will the public pay its just payment and the property receive its fair return and no more. This may be difficult or impracticable of exact accomplishment.

This means that interest on depreciation allowances should be at the same rate as the fair rate of return, and that this is the rate to use in computing annuities, and allowances under the compound-interest theory.

Accounting Depreciation, the Result.—As a result of approved accounting methods that include a reserve account and that have been used from the beginning, there will appear on the books at any given time a sum that may be called accounting depreciation. For those items maintained by the replacement method and for which reserves are not set up the sum will be zero, there is no accounting depreciation under this method. The Interstate Commerce Commission has recommended that reserves be established for all properties, and there is much to be said in favor of this recommendation. If a reserve account is set up, the balance in that account shows the amount of accounting depreciation for property in use.

If no reserve account is set up, there is no account that will show at once the amount of the accounting depreciation. The way to determine it is to compare the presently carried property statement with the original costs of the property in use, if these can be found;

the difference is the accounting depreciation for the methods of bookkeeping in use. Under the sinking-fund method, there should be no reserve set up against the property, but the balance in the trust fund reserve, which should in this case equal the fund, is the accounting depreciation.

Unless reserves are set up for all property, as has been recommended by the Interstate Commerce Commission, or a full depreciation fund is maintained, accounting depreciation can never agree with the depreciation present at any given time, but it should agree substantially with it for those units or items which are maintained from the beginning under depreciation allowance methods, if the estimates of service life on which the allowances have been based have been correct, and the property has worn at the rate assumed by the particular allowance method adopted.

The straight-line method will show at any time a larger accounting depreciation than either of the compound-interest methods.

Summary.—None of the allowance methods works out in practice exactly as indicated in the tables. Accidents, and errors of judgment in prophetic estimates of service life, may cause sums received for depreciation to be excessive or deficient, but, in the accounting of a continuing property, these differences can be adjusted from time to time.

In the opinion of the Committee, the several methods described are respectively more particularly applicable as follows:

The replacement method is applicable to those short-lived properties or parts of properties made up of a large number of items, the replacement or retirement of which proceeds after a time with fair regularity and causes no troublesome variations in return or service rates. Railroad ties are an example. Rails, when a part of a very large property, and machines where very many are owned and used, may also be handled by the replacement method. Although applicable to all such properties or parts of properties, the replacement method is at present undesirable because it may result in loss to the company owner in the case of a valuation, determined under an interpretation of the Knoxville decision, which holds that all loss of service life of physical items, except such as is made good by current repairs, is loss of value of investment, and that obligation of the public to pay can never be accepted as an asset to offset accrued depreciation.

The straight-line method of accounting applies to any property units having more than a year of service life, which are assumed to depreciate according to the straight-line theory. The compound-interest theory applies similarly to property units assumed to depreciate according to the compound-interest theory. Under either method it may be necessary to maintain a fund not invested in the property itself, as when the property is stationary or consists of only a very few large

units of long life. For such properties the sinking-fund method of accounting could be adopted, if the compound-interest theory is held to apply, provided it is fully understood and correctly applied, but it is not recommended.

The great discrepancy in the growth of depreciation of long-lived units under the straight-line and compound-interest theories should be carefully noted when determining which theory to use. For short-lived items there is not much difference, and in some cases the straight-line theory may result in more uniform annual payments than the compound-interest theory; but, as already pointed out, there is a very great difference in the results of the two theories when applied to long-lived units. For such units, the Committee believes that the compound-interest theory is more nearly in accord with the truth as expressed by the unit-cost theory, which is thought to give results most closely corresponding to actual depreciation, and here the compound-interest theory would seem best to apply.

The extent of the difference in the amount of depreciation under the straight-line and compound-interest theories, for property units having various lengths of service life, is shown in Table 4. It is to be noted that the first column shows the percentage of the total service life which has expired, and consequently the percentage of existing depreciation computed under the straight-line theory. The remaining columns show the corresponding percentage of depreciation under the compound-interest theory based on a 5% interest rate compounded annually. For example, when 20% of the life of a property unit has expired, the depreciation by the straight-line theory would be 20%, regardless of the length of life of the unit, but by the compound-interest theory the depreciation would range from 16.3% for a unit having a life of 10 years to 1.3% for a unit having a life of 100 years.

TABLE 4.

Percentage of total life which has expired = percentage of depreciation by straight-line theory.	Percentage of Depreciation Under Compound-Interest Theory, Corresponding to Percentage of Loss of Service Life Given in First Column.				
	10-year unit.	25-year unit.	50-year unit.	75-year unit.	100-year unit.
10	8.0	5.5	2.6	1.2	0.5
20	16.3	11.6	6.0	2.9	1.3
30	25.1	18.6	10.3	5.3	2.5
50	43.9	35.3	22.8	13.8	8.0
70	64.7	56.6	43.1	31.6	22.5
90	87.7	83.8	76.3	68.6	61.1

This report is particularly concerned with depreciation accounting as it relates to valuation, and the determination of the depreciation of valuation. It would seem to be fair in any given case to give

the method of accounting used by the utility in setting up depreciation allowances its proper effect in determining deductible depreciation or the depreciation of valuation. The foregoing discussion of the several more common methods is given in order that the proper effect of each may be better understood by the valuing engineer.

THE DEPRECIATION OF VALUATION, OR FAIR DEPRECIATION.

Cost of Decretion.—Finding the cost of decretion is a step in the determination of depreciation, but the result is not necessarily depreciation of valuation. By cost of decretion is meant the loss of service life of an item converted into loss of value. This produces what is sometimes called depreciation and what is depreciation for the particular item. As it may or may not be a quantity to deduct from cost or other base for value when finding value or "fair value", it is not called depreciation here, but cost of decretion, simply to avoid confusion likely to result from the use of the word depreciation in more than one sense.

The first step in estimating the cost of decretion is to make the necessary examination of the property unit by unit. This examination should include an investigation of every element that has any bearing on the future and past service of each item and the character of its maintenance. From the investigation an estimate will be made of the remaining service life of each unit under the method of maintenance being followed; its past service life will be known; from these its total estimated service life, which may or may not agree with assumptions made for past accounting purposes, is found. Examination should show also the efficiency of operation of each unit.

To estimate the fraction of service life consumed requires a knowledge of past service and an estimate of future service life. There are two questions of importance to be discussed in this connection.

1.—Treatment of Inadequacy and Obsolescence.—Experience furnishes a guide in the making of reasonable estimates of service life for those property units devoted to well-known operations, unlikely to be superseded by newly invented units to perform the same service, or to be rendered obsolete or inadequate by the changing requirements of a shifting population, or of commercial methods, or the changing habits and demands of the community. It is very difficult, in some cases, however, to make such estimates for property units which are likely to go out of service for one reason or another before they are worn out.

Nevertheless, it is recognized to be good business policy to make the best estimate possible in the light of such experience as may be available, and to fix a periodic allowance for depreciation reserve accordingly. Indeed, it is prescribed by the Interstate Commerce Commissions and many State Commissions, that the estimated effect

of inadequacy and obsolescence shall be included in the depreciation periodically credited to reserve by common carriers. Many State commissions make the requirement that these causes shall be included, not only in fixing the depreciation credited to reserve, but in fixing the amount of depreciation to be deducted in determining the "fair value" of a property.

Although the matter has not been definitely passed upon by the United States Supreme Court, some Federal and higher State Courts have recognized the propriety of including inadequacy and obsolescence as factors in the determination of depreciation.

The estimation of inadequacy and obsolescence is of necessity somewhat more speculative in character than the estimation of the results of wear, tear, and decay, but there is greater or less speculation in all estimates of future service life of physical property, and it would seem to be inconsistent to consider functional depreciation in estimating depreciation allowances to be charged to operating expense, and then to ignore it in a valuation.

The Illinois Public Service Commission, in the case of City of Springfield *v.* Springfield Gas and Electric Company (March 9th, 1916), in the course of a long discussion and review of the opinions of the Courts on this subject, says:

"Depreciation, accordingly, may be divided into two classes: physical, due to wear and tear; and functional, due to inadequacy and obsolescence which require replacement of equipment before it actually is worn out.

"It is the opinion of this Commission that the weight of authority compels a reasonable deduction from cost new for accrued depreciation —both physical and functional— * * *."

"In view of all facts in this case, the Commission finds that it is but reasonable, proper, and equitable to make deductions from cost new to cover accrued depreciation, both physical and functional, and that it is proper to treat depreciation consistently in all its features. Nothing in the record, and no theoretical consideration presented in this matter, are of sufficient weight to cause the Commission to depart from this reasonable and thoroughly consistent treatment of depreciation, which not only possesses judicial sanction but also is sound in both economic theory and business policy."

The California Railroad Commission, in the case of the Central Pacific Railway Company, decided December 8th, 1915, gives the following definitions which refer to functional depreciation:

"Physical depreciation is caused by the action of the elements and the wear to which a facility is subjected; functional depreciation is caused by the inadequacy or obsolescence of the facility, due to developments which have made it incompetent to perform its function properly or economically.

"Reproduction cost of a railroad less depreciation, in a valuation for general purposes, is the reproduction cost less the diminution in

the value of the physical elements of the property, due to use, age, *obsolescence, inadequacy,* or other causes, plus the increase in value of physical elements due to age or other causes." (Italics ours.)

In the case of the Chesapeake and Potomac Telephone Company of Baltimore City, decided March 8th, 1916, the Maryland Public Service Commission made the following statement:

"Any theory for ascertaining existing depreciation in the plant of a public utility which confines such depreciation solely to the actual, visible, physical, demonstrable deterioration which can be seen by the human eye and measured by the human hand, must of necessity ignore that other species of deterioration which the experience of the past has demonstrated beyond peradventure exists in the property of every telephone company, although it can not always be seen by the human eye or measured by the human hand.

"We refer to that tendency upon the part of all such property to become inadequate or obsolete with the lapse of time. We find it in the case of practically every building which this company owns. Ample, adequate to-day, they may become entirely inadequate to-morrow."

The Colorado Public Utilities Commission, in the case of the Colorado Springs Light, Heat and Power Company, decided March 1st, 1916, made the following statement:

"This Commission is familiar with the decision of the Idaho Supreme Court in Murray *v.* Public Utilities Commission, 150 Pac., 47, and with the theory there announced that there should be no theoretical accrued depreciation deducted from the reproduction cost of the physical property, but the court there states that actual depreciation should be deducted. Just what method an electrical engineer may use in arriving at the actual depreciated value of an electric property without considering theoretical depreciation is somewhat beyond our scope of vision."

A limited search of the practice of public service commissions indicated that inadequacy and obsolescence were included either in ascertaining the amount of depreciation to be included in earnings, or to be deducted from cost to obtain "fair value", by the commissions of the following states: Arizona, California, Colorado, Illinois, Maryland, Massachusetts, New York, Oregon, South Dakota, Wisconsin.

The Board of Public Utility Commissioners of New Jersey, in a decision concerning the rates of the Public Service Gas Company (1 N. J. Bd. P. U. C. 433, December 26th, 1912), distinguished between what is called, in its decision, theoretical depreciation, which must be sufficient to take care of obsolescence and that depreciation which can be determined by observation and inspection, and took the view that, in the future, allowance should be made for depreciation on the theoretical basis, but that as applied to an existing property, where it appears that the depreciation, credited to depreciation reserve in the past,

has not included the effects of inadequacy and obsolescence and thus been collected from the people, nothing should be held against the property for accrued depreciation due to these causes. The decision includes this statement:

"We believe that from this time forth allowance for depreciation should be made where possible, on the theoretical basis, but where depreciation has been charged off, the amount charged off appears to have been not theoretical depreciation, but merely amounts which would measure depreciation ascertained by inspection. We, therefore, conclude that we are on certain ground when the allowance for depreciation which is deducted from the cost to reproduce the property new is the amount representing the wear and tear and aging, and when we do not attempt to estimate the greater amount which would allow for obsolescence and inadequacy."

Although the matter of the inclusion of obsolescence and inadequacy has not been passed upon definitely by the United States Supreme Court, it is possible to infer from the language used in the Knoxville case and in the Minnesota rate case that the Court had in mind as a part of depreciation that due to inadequacy and obsolescence. In the Minnesota rate case the following language is used:

"As the Master said, everything on and above the roadbed depreciates from wear and weather stress. The life of a tie is from 8 to 10 years only. Structures become antiquated, inadequate and more or less dilapidated, * * * cars, locomotives and equipment, as time goes on, are worn out or discarded for newer types."

The use of the terms "become antiquated", "inadequate", "are discarded for newer types" clearly indicates that the master had in view depreciation from obsolescence and inadequacy, and although the Court quotes his statement it makes no unfavorable comment upon these features.

The decision in the Knoxville case contains the following language:

"But the reservoirs, the mains, the service pipes, structures upon real estate, standpipes, pumps, boilers, meters, tools, and appliances of every kind begin to depreciate with more or less rapidity from the moment of their first use."

Since about the only way that reservoirs can depreciate is through obsolescence, their inclusion in the foregoing statement, if not accidental, must have been based on a consideration of obsolescence.

A case in the Federal Court, recognizing the inclusion of functional depreciation in determining the sum to be deducted from reproduction cost, is that of the Des Moines Water Co. *v.* City of Des Moines (192 Fed., 193, 197, Sept. 16, 1911), in which it is stated:

"* * * the question is, What would it cost to-day to reproduce the plant? and from which, to get at the value of the present plant,

there would be deducted the value of depreciation, either by functional or physical depreciation."

In the Kings County Lighting Company case, the New York Public Service Commission for the First District included the effect of inadequacy and obsolescence in the determination of the amount to be deducted from cost for depreciation. When this case was appealed to the Appellate Division of the Supreme Court, that Court decided (People *ex rel.* Kings County Lighting Co. *v.* Willcox, 156 N. Y., App. Div., 603, May 9, 1913) to confirm the action of the Commission, but did not discuss obsolescence or inadequacy.

While most of the opinions of public service commissions and Courts in recent years have favored the inclusion of inadequacy and obsolescence, it is by no means uncommon to find in the opinions of masters and minor Courts, and sometimes of higher Courts, the expression of the view that all depreciation based on the life of a property unit should be excluded, and this would cover the exclusion of inadequacy and obsolescence. The basis in such opinions appears to be largely that, where the service is maintained at 100% efficiency, there is no depreciation. A recent opinion of this kind was that of the Supreme Court of Idaho (Murray *v.* Public Utilities Commission of Idaho, 150 Pac. R., 47, July 1, 1915):

"This Court is of the opinion that the rule of cost of reproduction less depreciation, adopted by the commission, is the correct general rule or principle to be applied in this class of cases. However, we believe that in ascertaining values in this way the worth of a new plant of equal capacity, efficiency, and durability, with proper discount for defects in the old, and the *actual depreciation for use,* should be the measure of value, rather than the cost of exact duplication.

"So far as the question of depreciation is concerned, we think deduction should be made only for *actual, tangible depreciation,* and not for theoretical depreciation, sometimes called 'accrued depreciation'. In other words, if it be demonstrated that the plant is in *good operating condition, and giving as good service as a new plant,* then the question of depreciation may be entirely disregarded." (Italics ours.)

Whitten, Vol. II., page 1150, gives a part of the decision of the Railway and Canal Commission of Great Britain concerning the value of the property of the National Telephone Company and its transfer to the Postmaster-General at the expiration of the Company's license on December 31st, 1911. (16 A. T. & T. Co. Com. L., 491, Jan. 13, 1913.) Whitten makes the following statement:

"Under the purchase agreement between the parties dated August 8, 1905, the purchase price was to be based substantially upon the reproduction cost of the physical property less depreciation.

"In this case the Postmaster-General contended that in computing the life of the plant for the purpose of estimating accrued depreciation,

the life period should be reduced on account of a probable shorter 'effective life' due to inadequacy, obsolescence, or other factors requiring supersession of a particular unit before it has been worn out. The greater stress was laid upon probable supersession through inadequacy due to the probable growth of the telephone business. The court held, however, that to give weight to these considerations involved a confusion of thought and that the possible and even probable growth of the Postmaster-General's telephone business had no bearing upon the present value of the Company's plant. The court, however, attempted to make due allowance for all functional depreciation actually existing in the plant at the time of the valuation."

The trend of opinion at the present time seems to be in favor of including inadequacy and obsolescence as factors in determining depreciation, both as to the sum to be deducted from cost to obtain cost less depreciation and as to the sum to be included in earnings. Until there shall have been authoritative court decisions in this country covering this matter, the estimator should proceed with caution, giving the property the benefit of any doubt, lest by mental speculation he destroy actual, existing value. Where the financial history of the property shows that the charges for depreciation have not included obsolescence and inadequacy, equity seems to require that they should not be included when determining the reproduction cost less depreciation of the property.

Under existing circumstances it is well to segregate the depreciation due to inadequacy and obsolescence from that due to other causes, that the propriety and effect of its inclusion may be weighed by the Court.

2.—Mortality Tables to be Used with Care.—It has been suggested already that remaining service life is determined as the result of examination and investigation; that depreciation is due to several causes, one or more of which may be chiefly responsible for loss of value in any particular case. The purpose of this paragraph is to emphasize this point and to suggest that ordinary mortality tables for physical properties are not to be carelessly used in this connection. The determination must be based on an investigation which includes not only age but character of past, present, and probable future service, character of past, present, and probable future maintenance, possible apparent or probable approaching inadequacy or obsolescence; and often the accounts must be examined to find the amount of money spent in repairs and general upkeep, and the regularity of the expenditure. Not only these but experience with other like properties under similar conditions should be considered, and sometimes properly prepared mortality tables giving estimated service life may be useful.

As has been suggested, many properties under proper maintenance will last forever, so far as human intellect can comprehend the meaning of that term.

That this is practically true, present existence of the following named structures seems to prove:

Main stone sewer, Rome	Built	600 B. C.
Arch bridge, San Angelo, Rome	"	200 A. D.
Several stone bridges at Nuremburg	"	1486-1728
Wooden bridge (Kapollsbrücke)	"	1333
Iron suspension bridge, Nuremburg	"	1824
Westminster Abbey, London, old portion stone	Built	13th Century
Hatfield House, England (Marquis of Salisbury)	"	1611—Stone.
Saint Lawrence Church (Nuremburg)	"	1477— "
South Church, Boston	"	1750—Brick.
Church, Alexandria, Va	"	1784— "
Howland House, Plymouth, Mass	"	1660—Frame.
Windmill, Nantucket, wood and shingles	"	1746— "
Washington's home, Mt. Vernon, Va	"	1784— "
Hobson's House, Montgomery, Ala	"	1815— "

On the other hand, apparently permanent structures have but a short life; what were new high buildings only a few years ago are already destroyed to make way for yet higher buildings. This means inadequacy and obsolescence. It shows that mortality tables based on the older structures are not applicable to the modern structures, and, based on averages, they would be likely to be far from the truth in any particular case.

At a recent meeting of railroad equipment officers from all sections of the United States it was determined from railroad records that:

"Obsolescence and inadequacy have been the cause of retiring practically all equipment in this country, and wear and age have not, except in very few cases, been the cause of retirement. There is, therefore, little data on which to base life tables, and as wear and age have not been the cause of retirement, experience is lacking which would permit the preparation of such life tables."

Although data may be lacking on which to base estimates of future loss of service life due to age and use, it would seem that, with all the data available with respect to inadequacy and obsolescence, there might be sufficient to estimate in a general way what the service life of railroad equipment is under varying conditions of service. Indeed, some such estimate must be made for any given road, in order to fix reasonable depreciation allowances for equipment as required by the regulating body. An estimate prepared with care for any given unit from a large number of data covering the service life of similar units would certainly be more trustworthy than one based solely on an examination of the particular unit. Tables showing the lives of certain units will be found in Appendix II.

Depreciation of Overhead General Expense.—Shall depreciation be estimated on overhead and general expense? The Committee believes

that the answer depends on the character of those expenses, and divides them into two classes: (1) Those which, like promotion expense, preliminary and location surveys, legal and other expenses, connected with the creation of the property, cannot be segregated into parts assignable to particular units, but apply to the property as a whole; (2) Those which would be incurred were the units to be reproduced, not as a part of a general reproduction, but for the maintenance of the property.

Expenses of the second class may be included sometimes in unit prices, but are not always entirely separable. Expenses of the first class cannot be thus included. The test as to whether or not a particular item of overhead shall be depreciated is: Will it be incurred in replacing units that are retired. If so, it is part of the cost of those items the service life of which is being consumed, and hence will be a part of the sum to be depreciated with the loss of service life of those items. If not, it is a part of the ever continuing property, and can suffer no depreciation except as the exchange value of the whole property may be lowered, in which case everything that went to make it loses value.

The Committee is of the opinion that all overhead charges which may be included in the unit prices of particular units, or which are specific charges against particular structures, should be depreciated, if the particular units or structures are to be depreciated, and as a part of the cost of those units or structures; that all overhead charges which would be incurred in replacement of units but which may not be easily separable in a reproduction cost estimate, should be depreciated by the average depreciation assigned to the units to which they belong; that overhead charges appertaining to the property as a whole and not to be reincurred in the replacement of units should not be depreciated at all, if the property is a continuing one.

Depreciation of Valuation Affected by Accounting Methods.—Decretion or loss in service life being always present in any going property, the cost of decretion is always present. Decretion is a fact, and is independent of methods of accounting, or character of regulation, but is much dependent on character of maintenance. In determining it, one is not helped in any way by reference to the accounting methods. He must examine the property units, estimate their remaining service lives, know their elapsed service lives, the character of their past service and maintenance, and the prophecy as to future service and maintenance. To estimate the cost of decretion one must know, also, the costs or estimated reproduction costs of the property units, but the amount of the estimate and whether or not it shall be treated as depreciation of valuation may be, and very probably will be, dependent, at least in part, on methods of accounting for depreciation

that have prevailed. Whether or not it will thus depend may also depend again on the character of public regulation.

(*a*)—Replacement Method.—If by order or sanction of a regulating body, or by long continued proper custom under no regulation, a property has been maintained in normal working condition, necessarily less than new in some or all of its parts, by the replacement method, and at any given date is being valued for any public purpose and at that date shows normal condition, all its several parts being in as good condition as could be expected, the accounts showing that always those amounts have been expended in renewals that were necessary to keep the property in normal working condition, and the fact appearing that no expenditure reasonably to be expected could put the property in better than the normal condition in which it is found, and that no unusually large expenditure is presently to be necessary for this purpose, then, in spite of the fact that there is an existing decretion in its several parts, there should be found no depreciation of valuation. Under the method of accounting, the public has not paid, and could not pay, for the accrued depreciation, and under this condition its accrued obligation to pay should be considered an asset of the company owner.

If parts of the property are maintained under the replacement method and part by some proper allowance method, then, except as noted below, depreciation of valuation should be found with respect to those parts maintained under the allowance method, but this depreciation of specific physical units will be made good in whole or in part by existing funds or property purchased with allowances, either or both of which will be included in the valuation as they are found.

Railroads are properties of the class just considered. Their owners have long maintained the greater part of their perishable properties by the replacement method, and, except for a comparatively recent requirement of allowances or reserves for equipment, this method has been sanctioned by the Interstate Commerce Commission. Therefore, for such properties as are found in normal condition, as suggested above, there will be no depreciation of valuation for those items maintained by the replacement method. If these items are found below normal working condition, there will be depreciation of valuation, sometimes called deferred maintenance, and it will be measured by the sum necessary to bring the items to normal working condition—not new, the initial decretion necessarily present in such items in normal working condition being ignored, but upon restoration to normal working condition, the integrity of the investment should be considered to be renewed.

If in the judgment of the valuing engineer, the replacement method may not be used with propriety for a given property, either because not in accordance with law, or because the method is not adapted to the property, then whether or not the property has been maintained in the

past under this method the valuing engineer should estimate depreciation in the amount of the cost of the decretion he finds. There can be no certainty that the property will be properly maintained in the future.

When a comparatively new property, other than a railroad, is to be valued, and it has not been under any regulation that has affected its accounting methods, the law as laid down in the Knoxville decision would seem to make it necessary to find depreciation of valuation in amount equal to the cost of decretion found for all items, whether or not maintained by the replacement method. The Committee, however, believes that this may work hardship and injustice in some instances, and suggests that in such cases the facts be reported with such recommendations as to equity, as may seem fair to the engineer.

The public utility is entitled to see that from earnings the value of the property invested "is kept unimpaired" and that "before coming to the question of profit at all, the company is entitled to earn a sufficient sum annually to provide, not only for current repairs, but for making good the depreciation and replacing the parts of the property when they come to the end of their life". This is a reasonable right, the existence of which permits of renewals of parts of a property, that can be called current repairs, under the replacement method.

(*b*)—Allowance Methods.—If either the straight-line or sinking-fund theory has been used in computing depreciation and the method of accounting for it has been prescribed by a regulating body or voluntarily followed by a company owner from the beginning, the same theory, so far as it applies to the property in question, should be used for estimating the cost of decretion, and the entire cost so found lessened by any accumulated depreciation funds will appear as depreciation of valuation, unless the sinking-fund method of accounting has been used. In the latter case, if the valuation has to do with the reasonableness of the return and the accounting is to go on as before, apparently-existing depreciation would not be *depreciation of valuation,* and therefore would not be deductable; but if the valuation has to do with condemnation or purchase, then, as in other cases, the apparently existing depreciation is depreciation of valuation, and the owner should receive the depreciated value of the physical property and the existing fund.

As has been said, the unit-cost method of estimating depreciation can hardly be used with convenience as an accounting method. When there has been no regular depreciation accounting method followed, the unit cost method for estimating depreciation at any given time may be used with fairness.

The Committee has advised that the proper interest rate to be used in computing depreciation annuities is the same as the fair rate of return. This advice pertains to present and future accounting.

If, however, an old property, that has been properly maintained under the sinking-fund theory, is to be valued, that rate of interest should be used in computing the growth of theoretical depreciation that has actually been realized and has produced the existing depreciation fund or reserve. If there has been no depreciation accounting and it is desired to estimate the accrued depreciation under the sinking-fund theory, the engineer may choose the interest rate, but, inasmuch as new accounting to be installed after the valuation or rates to be based on the valuation should include, in accordance with the Committee's advice, an interest rate for depreciation equivalent to the fair return rate on capital, it is suggested that this same rate be used in computing the accrued depreciation.

Effect of Investing Allowances in the Property.—Under the straight-line or compound-interest method of accounting it is contemplated that, so far as possible, the depreciation allowances shall be invested in additions or betterments to the property. If such contributions of the public toward depreciation of existing property are invested in betterments and additions, then there must be depreciation of valuation to whatever extent cost of decretion is found, because in the inventory the betterments and additions made with the depreciation allowances will be listed as part of the property to be valued just as are the original items, the depreciation allowances for which were used to provide the betterments or additions. There will be no offsetting funds, but there will be property contributed by the public which cannot be capitalized and for which credit can be given to the public only by deducting an equivalent depreciation.

If, at the time of any valuation, not all the contributions of the public toward depreciation have been re-invested in the property, depreciation of valuation should still be found in the amount of the estimated cost of decretion of the physical property, but this will be offset to such extent as other assets, such as cash or outside securities, are in hand representing the portion of allowances, not re-invested in the property, but held for this purpose, and which, therefore, should be inventoried and included in the valuation.

Effect of Regulation on Depreciation of Valuation.—Regulation which determines the method of accounting will in part determine the amount of depreciation of valuation when finding "fair value", because it determines the method by which the public shall pay for the loss of service life.

It has been said by the Courts that it is not possible to go into the unregulated past to find losses or excessive profits, but if there has been regulation determining the method of accounting for depreciation from the beginning, or for a long time, and this regulation has fixed the sums to be included in the earnings for depreciation, it should be permissible to inquire into the adequacy of these sums. It seems

clear that in this respect it is proper to go back into the past and inquire to what extent the public has compensated for the loss of value due to loss of service life. If the regulating body has prescribed the replacement method for the whole period that units have been in existence, then, although depreciation may exist, it is not depreciation of valuation, because, under the method of accounting, the public has not paid, and could not pay, for the accruing depreciation, and is still under obligation to pay for it.

Methods of accounting in force at the present time which make proper provision for the accruing depreciation should not have full weight, if, in previous years during the life of the property units, other methods were in use which did not make proper provision for such depreciation. The amount of depreciation of valuation in such cases should be equivalent to the accumulated contributions of the public for depreciation allowances under the various methods of accounting which have affected the property unit from time to time. The public is still under obligation to make good that part of the loss of service life not yet paid for, and this obligation should be considered to be as much the property of the company usable to offset accrued depreciation as renewal funds or property actually in existence.

Whether or not this reasoning will stand in any case is for the Court to determine. Valuing engineers and accountants should report what they find as to the actual cost of decretion, and the sums which have been received to offset such cost, under the methods prescribed by the regulating body from time to time. They may give their opinions as to the amount of depreciation that should be deducted from cost to find cost less depreciation as an element in the quantity known as "fair value".

If regulation has not fixed accounting methods, but has limited the earnings, it should be permissible to inquire whether the limited earnings have been sufficient to pay operating expense, depreciation, and fair return. If so, depreciation found should be considered depreciation of valuation to the extent warranted by the accounting methods lawfully or properly followed; if not, a question arises. It is remembered that the duty of the company owner is first to maintain the property "before coming to the question of profit at all", and that it is the duty of the regulating body to see that rates are such as to permit the company owner to earn operating expense, depreciation, and fair return. If the regulating body has made sufficient earnings impossible, is it still the duty of the company owner to maintain the property before paying fair return to its security holders? If it is, depreciation of valuation should be found in the amount of the total cost of decretion or so far as warranted by the accounting methods followed. If not, depreciation found should not be considered depreciation of valuation except to the extent covered by earnings after

deducting operating expense and fair return. This is a matter of equity to be determined by a Court, and the Committee will not venture an opinion. If under regulation the property is a losing venture, it is not included in the class of properties now being considered. The depreciation existing will be found and reported, together with all pertinent facts, and the Court will determine the equities of the case.

Concluding Suggestions.—The valuing engineer should bear in mind that when a company owner has invested a reasonable sum in a property for public service, it is entitled to, but not guaranteed, a fair return on its investment, so long as the money remains in the property, either as property, or funds, or accrued public obligation to pay. Therefore, so long as the company owner keeps a sum equivalent to the total investment at work for the public, either as property serving the public, or funds held in reserve for such property, no policy should be followed in estimating depreciation that will reduce the property to a value less than the investment, or, when using cost of reproduction less depreciation as a basis of "fair value", to a value less than the cost of reproduction of that part of the property estimated to have been created with company funds, acquired by gift or in any way not the result of public contributions to cover depreciation.

Valuing agencies should also bear in mind the fact that for 30 years, until 1909, the Supreme Court of the United States not only recognized the replacement method as a proper method for the maintenance of public utility property, but disapproved the practice of charging the public with depreciation allowances in advance of the necessity for their use, holding that only money actually expended could be charged in operating expense and so collected from the public. In 1909 the Court apparently reversed itself in the Knoxville case. For the purpose of the present discussion, there is no need to speculate as to the strict applicability of this decision to all kinds of properties or property units, but it is thought to be proper to advise that valuing agencies should proceed in such a manner with respect to depreciation of properties that grew up under the law as it was before 1909, so that such properties shall not be unfairly reduced in value by strict application of a current interpretation of the Knoxville decision to all their parts. If the law changes, equity would seem to demand that the change shall not be retroactive; and it may be said fairly, we think, that though law must in general govern in all matters on which it speaks, yet, with respect to such matters as the details of valuation of public utilities, of which depreciation is one of importance, in the determination of which there never can be more than approximate results, and concerning which the minds of men have been and are changing, equity should not be ignored.

Appreciation.

Definition and Application.—Appreciation, as used in connection with the valuation of public service properties, according to the definition given in the Glossary "is generally restricted to physical items, and measures their gain in value due to age, use, and properly directed labor. Its principal application in connection with railroads is to roadbed, which, for instance, is increased in value by solidification and grassing of slopes."

Appreciation, therefore, represents the improvement in quality and usefulness of certain parts of the physical properties of a railroad or other public utility property, and it results from the lapse of time from work not specifically charged to capital account, from maintenance, from use, etc., and covers items not represented either by the quantities, or unit prices, that are determined in connection with a valuation.

Upon a railroad, appreciation is found in connection with roadbed, both in cuts and fills and in the modification of embankments; the general improvement of the slopes through various forms of protection of both embankments and cuts; and improvement of drainage facilities along the roadbed, and right of way in general.

In the case of irrigation works, appreciation may be realized upon dams, canals, and embankments, particularly when not originally built with great care.

Its determination is difficult, and care must be exercised lest any of the allowances be duplicated in development expense.

General Principles.—In the case of the San Joaquin, etc., Canal Co. *vs.* Stanislaus County, *et al.*, 191 Fed., 875, in which was involved the value of certain canals, the Company claimed that the earthwork had appreciated in value, the claim being that, by the lapse of time and by reason of the packing of the banks and the silting of the canals, an additional value had come, in the way of avoiding breaks and in preventing the loss of water by seepage. Judge Morrow, in reviewing the findings of the master, quoted from various Supreme Court decisions to the effect that a public utility property is entitled to earn a fair return upon the reasonable value of its property, at the time it is being used for the public, and added:

"We then have this rule for ascertaining the value of a plant of the character of that owned by the complainant in this case: Find the cost of reproduction as of the date of the use in question and then from this cost deduct the depreciation that has occurred from age and usage."

The master to whom the case was referred having determined that depreciation should be deducted, said:

"Likewise it would seem to me that if by reason of a lessened amount of depreciation, the canals of complainant in their present

condition are capable of delivering more water, thereby producing greater revenues to the Company, it would be of more value than a canal estimated on the basis of the reconstruction figures aforesaid."

The master, however, was not satisfied with the evidence submitted as to the amount of depreciation or appreciation, and held:

"After a careful examination of all the testimony on this question I find that I am unable to make either a calculation as to appreciation or depreciation of the earthworks of the canal and shall assume that the one offsets the other."

Circuit Judge Morrow, when he reviewed the case (page 855), stated:

"After carefully reading the testimony on this subject I have reached the same conclusion the master did with respect to this claim."

In this case, therefore, appreciation was acknowledged; but the one was considered to offset the other.

In the Minnesota Rate case, where the value of railroad property was sought to be determined through the cost-of-reproduction method, and where the Court below found that appreciation and depreciation existed in practically equal amounts, so that the one offset the other, Justice Hughes stated, in settlement of the matter:

"If there are items entering into the estimate of cost which should be credited with appreciation this also should appear, so that instead of a broad comparison there should be specific findings showing the items which enter into the account of physical valuation on both sides."

It appears from this decision that there can be no general offsetting of appreciation against depreciation, but that appreciation must be determined separately from depreciation.

Determination and Estimation of Appreciation.—It is now conceded that all items that are measurable by units, such as rip-rap, protection of slopes by sodding or other forms of vegetation, in whatever manner it has been secured, should be measured and unit prices attached, and the value of rip-rap, sodding, and other forms of slope protection should be determined in that manner; and that this method should be followed in valuing common carrier properties, and other public service properties, such as dams, protected embankments of reservoirs, etc.

There are two forms of appreciation that are particularly applicable to railroad properties; one is described by the terms "Solidification and Seasoning", and the other by the term "Adaptation".

Solidification and seasoning are found in railroad, canal, and other embankments, and along the slopes of railroad cuts. They are produced by compacting under the action of the elements; through use, such as the running of trains of a common carrier; through the skillful

direction of labor, of a common carrier or other public service corporation, in checking wastes on the slopes of embankments, and encouraging the growth of vegetation:—the final result being a solidified condition of the entire roadbed or other form of construction with greater compactness in the case of banks, and the drying out of cuts and the solidification of the slopes of cuts. The results of solidification and seasoning are a reduction in the cost of maintenance of the property of any common carrier, or the property of any public service corporation that receives any form of protection due to age and the action of the elements, combined with properly directed maintenance labor. Rip-rap becomes more settled, compact and secure; trees and shrubs, planted for ornamentation or snow protection, increase in usefulness and value with age and care. In railroad property a higher value is evidenced by the fact that trains can be run at greater speed and with greater safety; and that the expense of operation is reduced, and fewer accidents occur, after many years have passed since the property was a completed new one.

It is generally conceded that appreciation in the form of solidification and seasoning continues over a long period of years. For example, a railroad 40 years old is much better than one 5 years old. In measuring all forms of appreciation which may occur, however, it is necessary to have a full knowledge of what methods have been used by common carriers in process of construction and in the period of physical development following the construction period. A railroad property is not a finished product when the construction forces have put its parts together and turned it over to the operating department. The subsequent work done upon it, and the quantities subsequently added to it to produce the finished product, should be covered by the cost of reproduction rather than under appreciation.

Take, for example, the Virginian Railway, 444 miles long; tracklaying was started in 1905; train service was begun on some parts of the line in 1907; operation was begun under difficulties in 1910; ballasting, etc., was completed in 1915. In the 8 years (1907 to 1914, inclusive), during which physical development period the first stage of solidification was in progress, the excess cost of ordinary labor per mile of track totaled $1 630.

Again, on the Big Sandy low-grade line of the Norfolk and Western Railway, 59 miles long, tracklaying was started in November, 1903, and operation was begun under difficulties in 1904, with some construction work in progress until 1907. During the 3 years of the physical development period, while some construction work was still under way and the first stage of solidification was in progress, the excess cost per mile of ordinary section labor was $3 090 more than that during the 3 years immediately following.

The items of cost in general maintenance labor, such as these incurred during the period between the beginning of the operation of any portion of a railroad and the final completion thereof by full ballasting, etc., which generally covers a period of several years, is an item of cost to the property, whether it is charged to construction accounts or not; and it most frequently has not been so charged in the past. Hence, in determining the cost of reproduction new of a property, this item of cost, which will vary in different sections of the country, as shown by the two examples, the extreme case given being in a difficult country, so far as control of slopes is concerned, must be added to the cost of reproduction as determined by measurable units. Care should be taken in analyzing these costs that they may not be duplicated in reproduction cost or appreciation and in development expense.

In addition to this, however, there is an increased value that comes to such a property by reason of solidification and seasoning, due primarily to time and use, that continues for many years after the entire completion of a railroad.

Adaptation.—Adaptation is the adjustment of the physical property to its environment and purposes, and is brought about in the course of time by the action of the elements combined with labor. For example, in the case of a stream, where by successive floods the stream may deepen and scour out its channel and make more safe adjacent embankments. After a railroad is in operation, many changes are made in roads and drainage, as between the railroad and adjoining lands, all traces of which are lost in a few years thereafter; likewise, culverts originally built are found to be too small and are necessarily enlarged, or the approaches and outlets are changed. Briefly, therefore, adaptation is exemplified in improvement in drainage, both on the right of way and outside the limits of the right of way, which has been made from time to time by the forces of the railroad company or other public service corporations, the value of which cannot be determined by measuring items of quantity at the date of valuation. It is an item of charge to the cost of reproducing a roadbed or dams, canals, and embankments of the class mentioned, of the drainage area in connection with the dam of a water company. This class of appreciation should be taken into consideration along with solidification and seasoning.

The best method of estimating appreciation due to solidification, seasoning, and adaptation appears to be by comparing the cost of maintaining a new road, directly after it has been entirely completed, with the cost of maintaining an old road in the same district under similar conditions of traffic.

In one case of a western railroad the cost of maintenance of a new line, 175 miles long, was compared with the cost of maintenance of an

old line of the same length. In 2½ years the excess cost spent on the new road, to make it comparable with the old one, aggregated $1 400 per mile.

Another way is to assign a direct percentage to the grading quantities.

In California allowance was made of 2% a year for 5 years on all earth and loose rock quantities, and 1% per year on all solid rock quantities, for solidification and seasoning. This might be used as a minimum, to which should be added $600 per mile for all roads more than 5 years old.

Care must be taken in estimating appreciation that items of labor and expense, included therein, may not be duplicated in development expense.

CHAPTER VII.

DEVELOPMENT EXPENSE.

The Nature of Development Expense.

The Committee recognizes two principal periods in the creation of a going concern operating a physical property for the production of a commercial commodity, be that commodity water, gas, electricity, sugar, textiles, or any other thing, or the transportation of persons, property, or thought. These two periods are:

1.—The construction period, which covers the interval from the inception of the enterprise to the beginning of regular operation.

2.—The development period, which covers the interval from the beginning of regular operation to the time when efficiency and profitableness of operation shall have been achieved.

Corresponding with the two periods recognized, the Committee divides costs into two classes—construction costs and development expense. The estimated cost of construction includes all costs incurred during the construction period, and, as will appear, may include certain costs incurred during the development period.

Development expense is of two kinds: (*a*) the cost of tuning up the physical property and bringing it to present operating efficiency; and (*b*) the cost of acquiring the business.

The cost of tuning up the property and bringing it to its present state of operating efficiency stops at the end of what may be called the physical development period, which is usually included within the development period as previously defined, and the cost may be included in the cost of construction.

The cost of acquiring the business usually extends throughout the development period, though there are cases in which a profitable business develops at the very beginning.

The physical development cost, which should be included as a part of the construction cost, comprises the items of work required to bring the property to an efficient operating condition, such as: the extra work required on new embankments to maintain tracks in proper operating condition; the cost of testing and sometimes of re-adjusting and remodeling all sorts of machines to make them operate properly, or to increase their efficiency; the making good of defects which have become visible after a property becomes operative; and a great variety of other expenses incidental to the first operation of a property, which are not incurred in subsequent years after that same property has reached full operating efficiency.

The Committee also recognizes going value, as defined by it, as quite independent of development expense, and discusses it in Chapter VIII on INTANGIBLE VALUE.

DEVELOPMENT EXPENSE AS A PART OF ORIGINAL COST.

On the basis of original cost, the development expense in any one of the early years when the earnings are deficient will be obtained by deducting the actual receipts from the gross amount that the owner of the property is entitled to earn in that year. Such gross amount is the sum of these items:

(*a*) The expenditures for operating expenses and taxes;
(*b*) A sum to offset the waste of capital through depreciation;
(*c*) A sum representing a fair return on the investment, including money, and the money value of services and of other considerations.

The difference between the actual and the fair gross receipts for the first year is the development cost for the year, which should be added to the investment at the beginning of the second year in order to obtain a basis for estimating fair return for that year. By following the same course for successive years, adding the development cost for each year until there is no further deficiency of earnings, a sum will be reached which will represent the amount of the investment at the end of the development period, and the difference between the investment at the beginning of operation and at the end of the development period will represent the development expense.

It should be noted that the development cost obtained in the manner recommended includes also the physical development costs of those years when the earnings were deficient. So far as possible, these should be separated from the total sum found, and included as a part of the construction cost of the physical property.

After the property originally built has attained adequate and steadily maintained earning capacity, the ordinary additions of subsequent years may involve little or no additional development expense, except for the cost of testing and tuning up plant units, because there will be no deficiency of earnings caused by such additions, but, from time to time, additions may be made of such magnitude that the earnings will again become temporarily deficient.

Losing Venture.—Fair dealing demands that the development expense actually incurred in tuning up and developing the business of a normal property be properly recognized, and the Committee believes there is no more equitable way of doing this under normal conditions than by including it as a part of the capital account. It recognizes, however, that there may be abnormal conditions under which this method should not be followed, as, for instance, where the net

receipts are unnecessarily low on account of bad management, or where bad judgment has been used in the location or design of the plant, so that the property is bound to be a "losing venture".

It does not seem desirable that the general rule should be modified because of these exceptions. In the application of the rule to specific cases, it will not be especially difficult to distinguish between profitable properties and distinctly losing ventures, but it may be difficult to distinguish legitimate development expense from the cost of bad management, in connection with those properties that are neither very profitable nor distinctly losing ventures.

Amortization v. Capital Charge.—It is sometimes urged that, although development expense is a real expense incurred in developing a property and its business, that part which is not a construction cost should be separated from other costs and repaid by means of earnings in excess of a fair return on the "fair value" of the property as soon as practicable after the business has increased to such an extent that excess earnings may be obtained by the maintenance of the previously existing rates. This requires the maintenance of the high initial rates for a longer period than would be necessary if the development expense is included in the return base.

When it is thus included, the deficiencies in the early years are made good by the greater earnings throughout all subsequent years, resulting from the larger return base on which earnings are predicated. The inclusion of development expense in the return base appears to have advantages in that it furnishes a more definite and simple method of accounting, and permits the adoption of normal rates at an earlier period than under the other plan. The cost of developing the business is just as much a part of the cost of producing the property, as is the cost of the physical items. Moreover, the Committee sees no reason, in principle or in equity, why this element of cost should be amortized, any more than the cost of the physical property.

Difficulties.—In the determination of development expense there may be difficulty in determining what is a fair return, not only because of possible differences of opinion as to what is a proper percentage to adopt as a return on investment, but because of the difficulty in determining a proper sum for the depreciation allowance to be used in computing the gross fair earnings. This difficulty is minimized if the attempt is made to determine these sums only for the first few years of the life of a property, when there is a deficiency of earnings, and is greatly increased if the attempt is made to determine the fair return and the proper depreciation allowances for a series of years, while the deficiencies are being offset. Practical attempts to determine the net excess or deficiency of earnings in a long series of years, in the case of properties of considerable age, have shown that a slight difference in the percentage assumed for the fair return will cause such very

great variation in the estimated development expense as to show that the method will not give trustworthy results when applied to most existing properties.

The Committee recognizes that public regulating bodies having control of both the accounting and the rate-making of the utility from the beginning of its operation may in the future adopt other methods which will offset such losses or amortize them, but these methods should not be applied to existing properties.

The Courts have ruled that the effects of regulation cannot be made retroactive, and that one cannot go into the "unregulated past".

Ames *v.* Union Pacific, 64 Fed., 165, 176 (1894). Mr. Justice Brewer. "The same rule controls if a railroad property is sought to be appropriated. No inquiry is open as to whether the owner has received gifts from States or individuals, or whether he has as owner managed the property well or ill, or so as to acquire a large fortune therefrom. It is enough that he owns the property, has the legal title; and so owning, he must be paid the actual value of that property. If he has done any wrong in acquiring or using the property, that wrong must be redressed in a direct action therefor, and cannot be made a factor in condemnation proceedings. These propositions in respect to condemnation proceedings are so well settled that no one ever questions them. The same general ideas must enter into and control legislation of the kind before us [rate regulation]."

Public Service Gas Co. *v.* Board of Public Utility Commissioners, N. J., 87 Atl., 651 (1913), which was sustained by the Supreme Court of New Jersey, 87 Atl., 657 (1913).

"But as we have indicated above, the business thus acquired must be regarded as a legitimate part of the property of the company. We cannot equitably project back into the unregulated past a nome of prices that might to-day be regarded as fair and adequate, and assume that actual rates exacted in the past, in so far as they exceed what are now deemed fair, have not lawfully become the property of the company. If these high rates in the past have been employed by the company to acquire an intangible property in the shape of extensive patronage, that expectation of patronage is theirs and on its fair value the company is entitled to a return. It may or may not be a subject of regret that regulation was so long deferred; but deferred regulation is no excuse for refusing at present to allow a fair return upon what is the lawful property of the company."

Therefore the Committee holds that development expense cannot fairly be assumed to have been amortized in the past in old properties by excessive earnings, and that it should be included in present valuation, whatever changes in policy as to future costs or increments in value may be made by the regulating body hereafter. Moreover, the Committee thinks that in future regulation it is sounder public policy not to amortize development expense.

The determination of the proper rate of return is a matter to be decided by the Courts or regulating bodies, and an engineer, in making an estimate of development expense in the manner recommended, should state the rate of return on which it is based, so that the Court or commission will have the means of modifying the estimate.

Development Expense as a Part of Reproduction Cost.

The foregoing discussion relates to development expense as a part of the determination of the original cost of a normal property, and, as it is a real cost in connection with the original property, it is also a proper element to include in reproduction cost, but the difficulties of determining the development expense of reproduction cost are greater than in the case of original cost, because of the assumptions which it is necessary to make.

Shall it be assumed that the development expense will be based on the conditions which existed when the various parts of the property were created, or on the expense that would be involved if the property were to be re-created under the conditions existing at the time of valuation? Shall it be assumed that the existing business is ready and waiting, or that it has to be re-acquired at the time of valuation?

If the property under consideration has grown by additions made from time to time, so that it is now several times as large as when originally constructed, there would be, on the basis of the conditions which existed when the property was created, a large percentage for development expense in connection with the original property, because there had to be an actual acquisition of business at that time; but, on the other hand, there would be a very small percentage of development expense attributable to the additions.

If based on reproduction under existing conditions, the development expense would apply to the entire property reproduced.

The Committee believes, as already indicated, that development expense is a real cost in the production of a going property, and that it should not be ignored in the reproduction cost. It is somewhat difficult of determination in any case, by reason of the necessity of distinguishing between proper deficits and deficits due to management, in ordinary properties which are neither very profitable nor losing ventures, but no such difficulty of estimation should prevent its inclusion, when present, and when its amount is estimated as well as possible. It is especially a feature of valuation which should depend on reasonable assumptions based on known occurrences in connection with the property under consideration or similar properties in other cases.

Attitude of Courts and Commissions.

Development expense has been generally recognized in recent years by both Courts and commissions, usually under the title of "going

value". Sometimes these bodies have used the terms "going value" and "going concern value" to represent the intangible values of a going concern as compared with a dead one, but many times the terms are used with a meaning corresponding to the definition of development expense given by the Committee.

Going Value (Development Expense) Discussed.—A very complete discussion of going value is given by Judge Miller of the New York Court of Appeals in the Kings County Lighting case (People *ex rel.* Kings County Lighting Co. *v.* Willcox, 210 N. Y., 479, March 24, 1914). He gives (at page 492) the following definition of going value, which agrees closely with the definition of development expense adopted by the Committee, and the decision, although using the term "going value", may be considered as relating to development expense.

"I define 'going value' for rate purposes as involved in this case to be the amount equal to the deficiency of net earnings below a fair return on the actual investment due solely to the time and expenditures reasonably necessary and proper to the development of the business and property to its present stage, and not comprised in the valuation of the physical property."

This case was one in which an appeal was made from the Court below, and four questions were asked. The one relating to development expense was as follows (at page 481):

"(1) Was the relator entitled, upon the facts shown in the record, to have the commission make an allowance for going value in determining the value of the relator's property used in the public service?"

The opinion is too long to reproduce in full in this place, but the more pertinent parts are as follows:

"It is now generally recognized that 'going value', as distinct from 'good will', is to be considered in valuing the property of a public service corporation either for the purpose of condemnation or rate making, but there is a wide divergence of view as to how it is to be considered."

* * * * * * *

"The difficulty of determining 'going value' will not justify the disregarding of it. Rate making is difficult. But that will not justify confiscation. The difficulty, however, will lessen, as it does in most cases, when we cease to think about the subject vaguely. What then, is 'going value', and how is it to be appraised?

"It takes time to put a new enterprise of any magnitude on its feet, after the construction work has been finished. Mistakes of construction have to be corrected. Substitutions have to be made. Economies have to be studied. Experiments have to be made, which sometimes turn out to be useless. An organization has to be perfected. Business has to be solicited and advertised for. In the case of a gas company, gratuitous work has to be done, such as selling appliances at less than a fair profit and demonstrating new devices to induce

consumption of gas and to educate the public up to the maximum point of consumption."

* * * * * * *

"To view the matter in another aspect, take the case of a public service corporation with a plant constructed just ready to serve the public. It is going to take time and cost money to develop the highest efficiency of the plant and to establish the business. Three courses seem to be open with respect to rate making, viz.: 1, to charge rates from the start sufficient to make a fair return to the investor and to pay the development expenses from earnings, a course likely to result in prohibitive rates except under rare and favorable circumstances; 2, to treat the development expenses as a loss to be recouped out of earnings, but to be spread over a number of years, in other words, as a debt to be amortized, that involves complications, but would seem to be fairer to the public and certainly more practical than the first; 3, to treat the development expenses, whether paid from earnings or not, as a part of the capital account for the purpose of fixing the charge to the public. The last course would seem to be fairest to both the public and the company, as well as the most practical.

"It may be, as is urged, that a well-conducted enterprise will charge the cost of developing the business to operating expenses, and that it would open the door to an overissue of securities to permit the capitalization of early losses. In answer, it is sufficient to say that we are dealing, not with proper methods of bookkeeping, not with the proper capitalization upon which to issue securities, but solely with the fair return which the company is entitled to receive from the public. Treating a reasonably necessary and proper outlay in building up a business as an investment for the purpose of determining the fair rate of return to be charged is far from holding that it should be treated as capital against which securities might be issued.

"We do not say as matter of law that the third course above outlined should be adopted as an original proposition. That may present a question of economics, depending on the particular conditions involved. The commission in this case had to determine the rate to be charged, not by a new company with no business, but by an old company with an established business. The first question, therefore, to determine on this branch of the case was whether the company had already received a fair return on its investment. If it had received such return from the start, or if in later years it had received more than a fair return, the public would already have borne the expense of establishing the business in whole or in part, and to that extent the question of 'going value' for the purpose of fixing a present rate would be eliminated; for it must constantly be kept in mind in dealing with this problem that the company is entitled to a fair return and no more. If it has already had it, that is the end of the matter. If it did not receive a fair return in the early years owing to the establishment of the business, a subsequent rate must allow for that loss or it will be confiscatory."

The conflict in view, expressed in the concluding sentences quoted above, and the earlier citation from the U. S. Supreme Court, in Ames *v.* Union Pacific, 64 Fed. 165, 176, (1894), is to be noted.

Nevertheless, the Federal Court decision has been reaffirmed in a long line of later decisions, and would seem still to hold, as the position of the highest Court of the land.

Conclusions.

The Committee recognizes development expense as a possible, usual, and, in most undertakings, an unavoidable real cost in the production of a normal going property, and as quite distinct from going value as defined by it, and discussed in Chapter VIII upon Intangible Values. It is measured in nearly all cases by the difference between the amount which the company is entitled to earn in the early years and the amount which it actually does earn.

On the basis of original cost, if the accounts are available, the development expense can be determined from the accounts, taken in connection with estimates of the proper sums to be allowed for depreciation and for fair return on the investment. If the accounts are not available, the development expense must be estimated on reasonable assumptions based on known occurrences in connection with similar properties. It is commonly the case that the general conditions existing when the original property was created can be ascertained with sufficient accuracy for determining whether or not there were early deficits and approximately their amount.

For ordinary additions to the original property, in the case of a prosperous company, there would be no deficiency of earnings, but, from time to time, large additions might cause a temporary deficit which should be taken into account.

As development expense is a real cost of producing the original property, it should not be ignored in the reproduction estimate, and the Committee believes this to be especially a feature of valuation which should depend upon reasonable assumptions based on known occurrences in connection with the property under consideration or similar properties.

A determination should be made in regard to whether the property under consideration is a "losing venture" which cannot earn a fair return on the "fair value" of the property. In such a case, development expense cannot be obtained, because it is based necessarily on the theory of a fair return. In such cases, also, the development expense is unimportant, because the return is independent of the "fair value" of the property deduced either from original cost or reproduction cost.

It is not to be assumed that merely because the property failed to earn an adequate return for a certain number of years, the project was a losing venture. Thus many, if not most, water-works properties built prior to the Nineties, generally required a period of well over a decade to develop normal revenue. Their growth was slow during

the first 15 to 20 years in many cases, nevertheless it cannot be doubted that higher returns could have been collected from their consumers in the majority of cases had it been possible to raise the rates.

Properties vary greatly in respect to the length of time required for developing the business. Some classes of property, like street railways in or between populous cities, may develop their business to a profitable stage in a very short time, but in other cases, as, for instance, a great irrigation project in the Far West, it may be well known in advance of construction that it will take many years to reach the point where profitable results can be achieved. The difference between properties in this respect is obviously to be ascertained by a study of their history and of the history of similar properties.

CHAPTER VIII.

INTANGIBLE VALUE.

In addition to the physical elements of property discussed in the foregoing chapters of this report, there are certain elements of non-physical character that must be considered, and their bearing on the valuation of public utility properties explained. These elements of value are called "intangible" for the reason that they cannot be itemized, measured, and appraised, like physical units, but must generally be estimated by a study of the income account, the possible growth or appreciation in value of property, and other advantages, existing and potential, that attach to the location, environment, ownership, or control of the particular property to which they apply.

Meaning of "Intangible" as Used in Valuation.

The term "intangible" is used in the current literature of taxation to mean bonds, notes, stocks, and money at interest, which, if owned by a corporation whose property is being appraised, must certainly be classed as tangible in the inventory. In the valuation of public utilities, the word "intangible" should be understood as being restricted to its essential meaning of something incorporeal, not capable of direct or exact physical measurement, and in this report its meaning will be thus restricted.

The word "value" has been used very broadly in discussions of valuation and in Court decisions pertaining to the subject. There is a distinctly intangible basis for some of its meanings, and the Committee deems it proper to include the analysis of the word in this chapter.

The chapter then will cover discussions under the following heads:

Value—in general;
Franchise;
Going Value—Going Concern Value;
Good Will;
Efficiency, Favorable Business Arrangements, Design;
Strategic Location;
Leases, Easements, Traffic and Operating Agreements, Water Rights, Strategic Advantages, Other Privileges.

Value, Tangible and Intangible Bases.

Value may be said to rest on both tangible and intangible bases. Some meanings of the word are "excellence", "importance", "utility", "worth". Other meanings are "the desirability of a thing, as com-

pared with the desirability of something else"; "the degree of want felt for a thing, as shown by the relation of supply and demand"; and, commercially, "the price at which a thing will sell". This last is the "exchange value" of this report.

Still other authorized definitions are "the cost to produce"; "the amount of labor necessary to produce". These two definitions furnish the tangible basis for computing the "physical value". The definitions leading up to exchange value furnish the basis for the conception of the intangible element of the term.

We see by this that the conception of the tangible element of the value of a thing rests on its proper cost or on its production, while the exchange value, which includes all tangible and intangible elements of value, rests on the output of the thing or on the results of its operation. Estimates, in money, of these two conceptions may be said to approach the same objective from opposite directions and in an *ideal* public utility, where the actual net returns are just equal to fair income on investment, the figures should be equal. Such equality is obviously a proper aim of regulation. We have then this equation as *ideal* for the *ideal public utility of the future* under constant public regulation from the beginning, but not applicable in general to presently existing properties nor to any property without corresponding contractual obligations—

Tangible value—that is to say, proper cost, including development expense, less "depreciation of valuation".	=	Exchange value—that is to say, dependable net earnings, after deducting a proper depreciation allowance, capitalized at a rate of return, fair for the property in question.

Courts and commissions have striven to establish just valuations of corporate properties for various purposes, such as: a base on which return on capital shall be computed, or on which taxes shall be assessed; a sale made to the public, or against which securities shall be issued. This base has been variously called "fair value", "real value", "reasonable value", "the present value", "actual value", "the value", etc. In the great majority of cases, the properties being considered have been those not under full and continuous regulation in the past; and, where the last member of our equation has figured out larger than the first, the authorities have frequently allowed something for the excess of exchange value over tangible value which has grown up around the nucleus of the latter. This excess, when existent, is called by the Committee the intangible value pertaining to the property. Such additions to tangible value will be fully discussed later in this chapter. The object here is to differentiate clearly between the nature of tangible and intangible values in general, and

to show that both have distinct and legitimate meanings, but that the term "value", standing alone, may lead to misunderstanding of meaning unless qualified by a modifying adjective.

A broad basis for separating tangible from intangible values is that the former can be ascertained from the proper cost while the latter can only be computed from a study of the results which may flow from the use of the properties in question.

Exchange Value.—Exchange value is the desirability of the property, estimated in money, where there is a ready market for properties of the kind considered; exchange value is synonymous with market value, and may be said to be the price which a willing and intelligent buyer will pay a willing and intelligent seller. In the case of a utility property furnishing service to the public, this price will be a function of its existing or potential dependable net earning capacity, or of the additional earning power that may accrue to its owner through the control of the property in question. It is the second member of the above equation. If the property is operating under a limited franchise, the limit will have a bearing on the dependable feature of the earnings or other advantages, and the price will be discounted accordingly. It will be influenced largely by the intangible element in the value of the business as well as by the tangible value of the property measured by cost.

Since exchange value is determined by a consideration of dependable income and beneficial results, existing and potential, it will automatically include all intangible values pertaining to the property, so that the value of franchise, going value (not development expense), goodwill etc., cannot be itemized separately in a schedule.

Fair Value.—The "fair value", of Courts and commissions is intended no doubt to meet the definition given in the Glossary: "A value which is fair to the parties affected". In very many cases where "fair value" has been determined by public authority it has been made up of the present cost value of the property, as nearly as that could be determined, with reasonable allowance for depreciation plus an addition for such intangible features as the controlling authority deemed proper to add to the tangible amount. It has been held time and again by Courts that the "fair value" of a public utility property cannot be determined by a mathematical formula, by which, it is reasonable to infer, is meant a precise estimate based only on an inventory of the physical property.

It will be noted that, in all cases where additions of an intangible nature have been made to the physical inventory, such additions have been in very round numbers; like $285 000 in the Kansas City Water case; $40 000 in the Newburyport Water case; $75 000 in the Gloucester Water case; $150 000 in the Bristol and Warren Water case; $15 000

in the Galena Water case, etc. The roundness of these sums suggests that they were not arrived at by mathematically capitalizing earnings, but by some process of compromise or adjustment which seemed equitable to the Court.

In no recent case before the higher Courts has a valuation been fixed for a public utility property by capitalizing earnings to the exclusion of consideration of its tangible value measured by cost. This procedure seems rational, for the reason that the "fair value" sought by the Courts and commissions is wanted for some purpose of regulation; and, as the object of regulation is to secure justice for both the owners and consumers, it is not conceivable that a value based simply on a consideration of the present or estimated net earnings could be taken as a just base for any of these purposes.

Present earnings may be too low to command capital or to maintain the existing enterprise, or higher than the service rendered may warrant. They are often adventitious, empirical, and based on what the patrons can or will pay. To use them as the sole basis for determining "fair value", would be to render regulation nugatory.

If it is held that fair earnings, for the property as a whole, might be assumed as a starting point, it is pertinent to inquire on what such earnings should be based, or how should they be assumed. It is difficult to use value of service, to the consumer, *per se*, because it cannot generally be computed or assumed, as it is generally intangible and without a basis from which to start. Heat and electric units, energy measured by horse-power and similar units, are constant the world over, and of service to mankind; but no one would claim that their money equivalent is the same everywhere. An inland city of New England, for instance, should pay far more for such units than should a city at the pit-mouth of a coal mine in West Virginia. This illustration means that the cost of service should gauge, to a greater or less extent depending on circumstances, the price or value of it. A substitute plant might furnish service at a less cost, but it has been shown that substitute plants do not generally furnish a safe criterion of value. Hence—in view of the impracticability of assuming fair earnings, and the difficulty, if not uncertainty, attending their computation by other means—the cost of service, as produced by the plant under review, should be accepted as generally the most significant measure of the value of the service, and of the fair earnings to be derived therefrom. The reasonable value for regulation purposes must be largely deduced from the cost basis, with proper consideration of all the attendant circumstances and conditions—as for instance, the value of water rights in regions where water for irrigation has come to have, in fact, a commodity value.

In the opinion of the Committee, *"fair value"*, that is say, the valuation to be assumed in regulation, should be deduced in each case

as it arises, giving full recognition to the tangible values existing in the property, however acquired, and full recognition to the intangible values, so far as they are applicable to the purposes in mind; that *exchange value* should be deduced largely by a consideration of the beneficial results flowing, or reasonably expected to flow, from the use of the property; and that when the word *"value"* is used alone, the text or modifiers should show clearly, and to the extent that may be equitable, whether tangible or intangible value, or the sum of the two, is meant.

Franchise.

This term is defined in the Glossary as:

"The authority granted by government to a person or corporation to create and operate a public service property, to use public property, and often to condemn property."

A franchise of this kind frequently, either explicitly or by implication, grants protection from competition by similar enterprises.

Various Functions.—A franchise is said to be perpetual when it is so granted, or when granted for a very long period; limited, when its term is relatively short or definitely stated; and terminable, when it may be revoked at any time. Terminable franchises are often perpetual in fact, and are sometimes called "indeterminate franchises".

We may divide the possible functions of a franchise into three parts:

1. A license to do business, to operate a public utility, for instance, taking toll from consumers for its output;
2. A grant to use public property, like streets, for subways, pipes, tracks, overhead wires, etc.;
3. A protection from competition.

Generally, in the past, a franchise has been a free grant from the public, and the obvious inference is that the grantee shall perform the service contemplated at a rate to the public such that only a fair return on the capital and effort expended will be secured, including of course proper recognition of the risk involved. If it were supposable that consideration of a franchise would add materially to the capital base, so that rates for service would thereby be enhanced above a fair return, we should be confronted with the anomaly of the public granting a corporation the right of unlimited usury in its dealings with the public.

Court Decisions.—A leading decision of the United States Supreme Court, not concerned with rate regulation, plainly asserts that the franchise has value. In this case (Monongahela Navigation Co. *v.* United States, 148 U. S., 312, March 27, 1893), the Court said:

"So before the property can be taken away from its owners, the whole value must be paid; and that value depends largely upon the productiveness of the property, the franchise to take tolls."

This was a case of the United States taking over from the Canal Company a very old property, and the total award, which was much greater than the cost of reproduction of the physical property, was based on the profitableness of the plant.

In the New York Consolidated Gas case (Willcox *v.* Consolidated Gas Co., 212 U. S., 19, January 4, 1909), relating to rates for gas, the question of the value of franchises was treated at considerable length. This company was created by the consolidation of seven independent companies in 1884, and at that time the State authorities sanctioned the issue of additional capital to represent the value of the franchises as then determined to a sum amounting to $7 781 000. Later, in 1907, the value of the franchises of the company was under consideration, and it was assumed by a master in one case, and by the Federal Court in another, that the franchises had increased in value from the sum above stated to $20 000 000 and $12 000 000, respectively, the increase corresponding to the increase in the value of the physical plant. The United States Supreme Court, in 1909, sanctioned the continuance of the original $7 781 000 of franchise value allowed by the State authorities in 1884, for the reason that its capitalization had been authorized at that time, but it refused to allow any increase of franchise value due to growth of business after that time. The caution as to precedent contained in the second quotation below shows that the Courts are reluctant to recognize the propriety of capitalizing franchise values. The Court said (at pages 44 and 48):

"It cannot be disputed that franchises of this nature are property and cannot be taken or used by others without compensation."

"What has been said herein regarding the value of the franchise in this case, has been necessarily founded upon its own peculiar facts, and a decision thereon can form no precedent in regard to the valuation of franchises generally where the facts are not similar to those in the case before us. We simply accept the sum named as the value under the circumstances stated."

In the case of Kennebec Water District *v.* Waterville (97 Me., 185, December 27, 1902), the Court said (at page 218):

"It [defendant's claim] is that the value of a franchise depends upon its net earning power, present, prospective, developed and capable of development, at reasonable rates, that the value to be assessed is the fair value to the seller and not the buyer, and that 'just compensation' means full compensation for everything or element of value taken. * * * The appraisal must be made having in mind what we have already said concerning the character and duration of the franchise

and reasonableness of rates. While with these limitations, the owner is entitled to receive the value of the franchises, having reference to their prospective use as now developed, and to the future development of their use, consideration must also be had of the fact that further investment may be necessary to develop the use, and of the further fact that at any stage of development the owner of the franchise will be entitled to charge only reasonable rates under the conditions then existing. But, subject to such limitations, we think it should be said that the owner is entitled to any appreciation due to natural causes, such as, for instance, the growth of the cities or towns in which the plant is situated.

And further (at page 220):

"But we cannot assent to the proposition that the capitalization of income even at reasonable rates can be adopted as a sufficient or satisfactory test of present value. Such a capitalization would fix at the present time a specific value which would continue for all time to come, as a fixed and unvarying source of income, no matter how conditions may be changed."

In Spring Valley Water Works *v.* San Francisco (165 Fed., 667, October 7, 1908), the opinion, in discussing the question of franchise value in a rate case, after stating that a franchise, if it has value, should be taken into account in rate regulation as well as condemnation proceedings, said:

"Serious and perplexing questions arise when it is attempted to ascertain the value of the franchise and going business. Here very little has been settled by the Courts, except that each case must depend on its own special circumstances."

In these and other cases the Courts recognize the propriety of including intangible elements of value, but the reasonableness of the rates from which these values are derived is strongly insisted upon. In the case of the Monongahela Navigation Co., a very old property was at bar, and evidently great consideration was granted to long-accepted rates unaffected by regulation, on one hand, and, on the other, to the property rights growing up from these rates on the "innocent owner" idea. In general, the Courts have laid down no rule for fixing reasonableness of rates in these cases, nor for computing the value of a franchise.

Considering the money value of a franchise: as a license to do business, its value is vital, and cannot be measured in money; it is comparable to the value of the air we breathe; as a grant to use public property, it may carry with it costs, rent, fees, or obligations, the cost of which can be estimated. Such costs can hardly be called intangible, and should certainly be included in an inventory. Such a grant may also lessen the expense of installation which would be necessary if streets, etc., could not be used by the utility. This acts

to reduce the necessary investment. The third possible feature of a franchise, protection from competition, is the one that has probably given the principal money value to franchises in the past. It is the legal base for the monopolistic rights of corporations, and is the feature that calls for public regulation more than any other. Intangible values acquired under this phase of franchise have been recognized by the highest Courts to be the inalienable property of the present owners, as shown above, but, unless such values have been converted into physical property useful to the utility, the Courts are now very chary about admitting them to capitalization, as may be seen by the second quotation from the Kennebec Water District case given above. In fact, the principles of fundamental equities would seem to prohibit earning on intangible capital which is admittedly derived from anticipated earnings in excess of a fair return.

In fixing upon the "fair value" for a property, the license feature of a franchise can hardly be included; neither can the privilege to use public property, except so far as such privilege costs the grantee money. In fact, the grant is made purposely to lessen the otherwise necessary capital, and it would certainly be absurd to augment the capital by assuming an intangible value for the grant. The monopolistic feature is then the only base for intangible value pertaining to a franchise; and this cannot be computed separately from that arising from "going value" which will be discussed in the next section.

Going Value—Going Concern Value.

In very many discussions and Court opinions, this component of value has been hopelessly and blindly mixed with development expense, which latter the Committee has set up as a distinct feature. Clearness of understanding will be enhanced if the separation is adhered to.

Development expense is equivalent to expenditure of capital. Going value, on the other hand, is, in the minds of many, apparently, an indefinite something that a live business has, which a plant without business has not. The fact that a business is connected with its customers, house connections made in a water supply system, the breath of life put into the body, as some express it, seems to have an almost mystic significance to many. It has been called the soul of the enterprise, while the physical plant is the material body.

In the work of Henry Floy, entitled "Valuation of Public Utility Properties", 1912, the subject is discussed under four heads, at page 137 and following. These conceptions briefly and clearly set forth the different methods that have been adopted for discussing going value in rational terms and for measuring it in money.

They are:

First.—"A legal and economic, recognized value, usually determined in an approximate way, in addition to, and over and above the

value of the physical plant, resulting from the putting of said plant into actual and useful operation. The value may be based on merely an actual expenditure in dollars, or an estimated value indicating the worth of the service performed, in transforming the 'dead' into a 'live' income producing property."

Second.—"A very frequent use of the term 'going value' is that of 'capitalized losses', namely, the capitalization of losses incurred during the first few years after a corporation begins business."

Third.—"Going value has also been used to mean the value that obtains from capitalizing the present net earnings of a corporation, *i. e.*, the value of a created income."

Fourth.—"Although the trend of modern movement is toward the reduction rather than the creation of non-physical values, going values have been allowed, particularly in water-works appraisals, based on the present worth of estimated earnings including those of future business growth.

"The method consists in estimating the present worth of excess earnings of an existing plant compared with those of a hypothetical plant, between the date of valuation and the time the earnings of the assumed plant shall equal those of the existing plant."

These four interpretations cover the ideas that have been rather vaguely expressed by Courts, commissions, authors, and others, perhaps as well as they can be covered.

It will be seen that the first, second, and fourth are really founded wholly or in part on a conception of what the Committee has classed as development expense; and that the third is the "exchange value" of this report.

A careful reading of Court decisions, attorney's briefs, and opinions of engineers and authors on this subject, leads to the impression that lawyers and judges have generally leaned toward an appreciation of the intangible nature of going value as something inherent in a "system in successful operation and earning a revenue", while engineers and authors generally are disposed to look upon it as the cost of developing, not only the capacity to earn, but the market for the output as well.

Mr. Justice Brewer, National Water Co. *v.* Kansas City (62 Fed., 853, July 2, 1894), said:

"The fact that it is a system in operation, not only with a capacity to supply the city, but actually supplying many buildings in the city —not only with a capacity to earn but actually earning—makes it true that 'the fair and equitable value' is something in excess of the cost of reproduction."

On the other hand, Mr. Benezette Williams, in connection with the Dubuque Water-Works appraisal said, regarding the valuation of the Kansas City Water-Works, after describing the appraisal of the physical property:

"The commissioners, however, took into account the fact that the plant was in actual operation, with an established business and a long list of patrons, and added to the cost of replacement, which included a liberal allowance for contingencies, an allowance for interest on the investment for a time long enough to enable the business to reach the point at which it was found."

These two quotations typify the difference of conception that exists between many students of this subject. The first implies that the judge's conception of the amount to be allowed above reproduction cost was of an intangible nature, presumably to be determined by a study of the income. The other, representing more generally the engineer's view, based this addition on what the Committee considers tangible grounds of interest during construction and development expense. The Committee aims to clarify the subject by assigning all costs like those referred to in Floy's first class, as above, to the appropriate items of the reproduction schedule, and by classing the costs and losses of the development period as development expense and confining going value strictly to its intangible aspect, depending on a study of the income account which reflects the advantages accruing from enlarged business, social growth, and other factors of improvement and progress. Floy's third class does not exactly define the Committee's idea, because it means the whole exchange value of the property, while the Committee considers going value to be a sum that may be, under some circumstances, added to the appraisal of the physical property. It is the difference between the exchange and physical values, and includes and is the resultant of the intangible values pertaining to all the features discussed in this chapter. No division is possible between the value of franchise, favorable location, good-will, or the other elements of advantage. Their effects automatically add together to make up what is distinctly going value.

If, from the actual net earnings for a given year available for distribution there is subtracted a fair return on the reproduction cost, including therein all proper overhead charges, development expenses, and other tangible capital items, including appreciation in value, less "depreciation of valuation", the remainder will be a measure of the income from going value for that year. Whether or not such income may be capitalized and added to reproduction cost is debatable. If the remainder, thus obtained, is not zero, its algebraic sign will determine whether the going value is positive or negative in the case under review.

Going value derived from large earnings is legitimate and inevitable in competitive utilities, like the steam railroads of this country, steamship lines, and most manufacturing enterprises, the favorable location and good management of which give them advantage over rivals less favorably conditioned. In competitive enterprises the

favorably located and well managed one will naturally and properly receive a higher rate of return on its cost than the other one.

When several properties are to be combined in a single corporation, their exchange values seem to furnish the principal basis for adjusting the financial ratios between them.

Good Will.

This feature is defined as follows in the Glossary:

"In ordinary business, the good will represents the special value that a business has by reason of its popularity and the amount of business thereby attracted. It is a part of the value of a 'going concern'."

As applied to a department store or to professional practice, goodwill is a large item of intangible value. In some kinds of competing utilities it undoubtedly has weight. Its effect in any case merges into the resultant described in the last section, and the conditions accruing among competitive utilities are the same with this as with going value. In monopolies the highest Court has decided that good will is not an element to be considered independently in the valuation. In the case of Willcox *v.* Consolidated Gas Co. (212 U. S., 19, January 4, 1909), Mr. Justice Peckham said:

"We are also of the opinion that it is not a case for a valuation of 'good will'. The master combined the franchise value with that of good will, and estimated the total value at $20 000 000.

"The complainant has a monopoly in fact, and a consumer must take gas from it or go without. He will resort to the 'old stand' because he cannot get gas anywhere else. The Court below excluded that item, and we concur in that action."

Efficiency—Favorable Business Arrangements—Design.

These features are important, and, together with good management, should be encouraged. They add largely to the intangible value of a property; being, in fact, a major factor in going value which has been discussed above.

It is often said that efficient, economical management is not encouraged by regulation; but this should not be the necessary result. The English method of gas company regulation called the "London Sliding Scale" is perhaps the most prominent attempt to encourage efficiency that has yet been tried. It was adopted in 1904 by a Legislative act of the State of Massachusetts in an arrangement with the Boston Consolidated Gas Co. At that time the price per thousand feet of gas was fixed at 90 cents, and the dividend to the stockholders of the company at 7%, and the provision made that if in any year the price was reduced below 90 cents the rate of dividend for the succeeding year might be raised one-fifth of 1% for each cent of reduction below 90 cents. Provision was made in the Act for creating a surplus fund, if the earnings were not entirely exhausted by the dividends allowed,

and for increasing the price to consumers, if necessary in the judgment of the Gas and Electric Light Commission. The Act, following English precedent, provides that additional stock may be issued with the approval of the commission, but such issue shall be sold at public sale under competitive bids; also that the standard price, the scale, and the dividend rate shall be subject to readjustment after ten years from the passage of the Act. At present (1916) the price of gas under this arrangement is 80 cents and the dividend rate 9 per cent. The regulating board has radical changes in the method of control under consideration. In England the scheme has been in operation for thirty years or more, and does not work with entire satisfaction, except for a limited number of years after its adoption. In some cases the companies have not increased dividends as the scale allows them to do, evidently on account of the possibility of competition from other producers. This shows that natural competition, left free to act, is the real regulator where competition may exist.

Though the group of factors named in the caption of this section adds greatly to the exchange or market value of a property, they cannot in general be separately included in an inventory of either original or reproduction cost; but where exceptional efficiency in design, construction, and management is manifest, its results, although intangible, should be recognized and encouraged by the regulating body.

LEASES—EASEMENTS—WATER RIGHTS—TRAFFIC AND OPERATING AGREEMENTS—STRATEGIC LOCATION AND ADVANTAGES—AND OTHER PRIVILEGES.

These are often elements of substantial value. They are entitled to careful analysis and consideration in accord with their just dues. They are in the nature, however, of special problems, often highly complex and legal in character, varying greatly with locality, environment, and attendant circumstances. Therefore they will not be discussed in detail herein.

CONCLUSION.

With reference to intangible value as a whole, the Committee takes the ground that, in finding original or reproduction cost, there must be included first, the *tangible* elements (including development expense) to which cost can be assigned or which can be separately scheduled, with an attached value based on concrete facts; and, second, that pertinent facts, bearing upon the *intangible* values, should thereafter be developed independently, as an aid to the formation of sound judgment as to their value.

Exceptional efficiency—although practically difficult of recognition and compensation in any plan of valuation, and outside of strict engineering analysis—should be recognized by Courts and commissions, when appraising property.

See SINKING FUND.

Amortize.

To extinguish a liability or debt by means of a sinking fund. The word, however, is frequently used in connection with such extinguishment by other means.

Annuity.

An annual allowance or payment; generally an equal sum each year, such as the payment to a sinking fund.

Appreciation.

A general definition is gain in value or worth. As used in connection with the valuation of public service property, this term is generally restricted to physical items, and measures their gain in value due to age, use, and properly directed labor. Its principal application in connection with railroads is to roadbed, which, for instance, is increased in value by solidification and grassing of slopes.

The appreciation in land values will be called an *increment.*

Average, Weighted.

See WEIGHTED AVERAGE.

Betterments.

Physical changes in roadway, structures, facilities, or equipment, the object of which is to make the properties affected more useful, efficient, or safe, or of greater capacity.

Book or Accounting Cost.

Under COST—INVESTMENT.

Capital.

"A portion of wealth which is set aside for the production of additional wealth.

"While this is the sense in which the word 'capital' is used in economics, in bookkeeping the term 'capital account' is often used to mean assets on the credit or passive side which denote proprietorship."*

Working Capital.—The capital in the form of cash, stock on hand, and other current assets, which must be kept available for the operation, maintenance and administration of a property.

Capitalization Base.

Under VALUE.

Charges.

See OVERHEAD CHARGES.

Charter.

A grant of power by the proper authority to a group of individuals to become a corporation, in order that they may act as a unit for a specific purpose.

Compound-Interest Method.

See under DEPRECIATION ACCOUNTING.

Construction Period.

That part of the production or reproduction period extending from the inception of an undertaking to the completion of its construction and the beginning of its regular operation. The definition may apply either to a whole property, or to substantial parts of it constructed at different times.

This period is followed by the *physical development period,* in which are incurred construction costs necessary to bring the physical property to its present operating efficiency. (See Reproduction Period.)

Cost.

Cost-Investment.—In the case of a new public service property, in which nothing has been added or abandoned, the outlay incurred in creating the property, not only money outlay, but also the money value of services rendered and of other considerations involved.

In the case of old properties to which many additions have been made, and wherein many items of property have been worn out and replaced one or more times, either in kind or otherwise, these words, when not qualified, have no generally accepted meaning, and have been used by the Courts, commissions, and others in a very loose way.

* From "The Accountancy of Investment", by Charles E. Sprague.

The words are frequently qualified, as, for instance, original cost, actual cost, original cost to date, original cost plus improvements, but even these qualified terms appear to have no generally accepted meaning.

Book or Accounting Cost.—The cost as shown by the books. This necessarily depends on the method of bookkeeping used. It is frequently the case that book cost fails to include the value of services rendered in promotion and construction, for which no money payment was made, and such costs as those due to additions and betterments, interest on capital during construction, and the bringing of the property to its full present condition of operating efficiency, which may have been paid for, out of earnings or otherwise, but properly belong in the capital account. On the other hand, it may include charges for replacements which do not properly belong to the capital account, and may continue to include investment in property which has been retired without being credited on the books.

Cost of Reproduction—Reproduction Cost—Replacement Cost—Cost of Duplication.—The estimated cost of reproducing the property without deduction for the loss of value due to age or other causes.

Original Cost—Original Cost to Date—Original Cost Plus Improvements—Actual Cost.—These terms are often used interchangeably, though suggesting different things. The Committee believes that "original cost to date" and "actual cost" are the better terms and defines them as the cost of the original construction, plus all charges against capital proper, under approved accounting principles, for expenditures incurred thereafter, and minus all proper credits to capital for the cost of property which has been disposed of or otherwise retired.

Under this definition the "original cost to date" or "actual cost" of a property is the first cost of the identical property units now in use, including overhead charges. The former is a term used in the Federal Valuation Act, and may be authoritatively defined by the Interstate Commerce Commission.

Cost of Reproduction.

Under COST—INVESTMENT.

Current Repairs.

See REPAIRS.

Decrement.

See DEPRECIATION.

Decrepitude.

Decretion.

Under DEPRECIATION.

Deferred Maintenance.

A technical term used in connection with public service properties, representing the amount which must be expended in repairs and renewals to bring plant units to an operating condition normal for the character of service to which they are devoted.

Depletion.

Under DEPRECIATION.

Depreciated Value.

See *Remaining or Depreciated Value,* under VALUE.

Depreciation.

A general definition is lowering in value or worth. As used in connection with the valuation of public service property, it is the loss of value due to age and use, including the loss from deterioration, wear and tear, inadequacy, obsolescence, depletion, and other similar causes.

Discussion of depreciation generally includes, also, causes of loss of value or worth, and methods of depreciation accounting and of restoring the loss to the property or its owners.

The depreciation in land values will be called a *decrement.*

Accrued Depreciation.—Depreciation which has taken place. It may have reference to existing property only, or it may include also the abandoned property.

Decrepitude.—A term sometimes used in connection with public service properties as having a meaning similar to deterioration.

Decretion.—Loss of service life.

Deferred Maintenance.—See DEFERRED MAINTENANCE.

Depletion.—Permanent loss of value due to exhaustion, or permanent lessening of value, as, for example, of mining properties.

Depreciation of Valuation or Fair Depreciation.—The sum which should be deducted from original cost to date or from estimated cost of reproduction new, as a step in finding that which the courts have called "fair value".

Deterioration.—Reduction in the quality of a property unit or in its efficiency for service, due to its physical condition.

Fair Depreciation.—See DEPRECIATION OF VALUATION, *supra.*

Functional Depreciation.—Depreciation due to inadequacy, obsolescence, and supersession.

Inadequacy.—The insufficiency of a unit to perform fully the function required of it.

Obsolescence.—The condition or process by which units gradually cease to be useful or profitable as a part of the property, on account of changed conditions.

Physical Depreciation.—Depreciation due to deterioration, such as use, wear and tear, accident.

Supersession.—The substitution of a more profitable or efficient unit for the existing property unit.

Wear and Tear.—The physical deterioration of a property unit occasioned by its use.

Depreciation Accounting.

The branch of accounting by which loss of value is provided for or accounted for either wholly or in part. There are various methods, among which are:

1.—Replacement Method.—This method makes provision from the earnings for reimbursement for the cost, less salvage, of property units retired when they reach the ends of their service lives, whether for replacement or for any other reasons.

2.—Sinking-Fund Method.—This method makes provision from the earnings for equal annual depreciation allowances of such size for any property unit that if these allowances are invested in a sinking fund they will, *with accumulations of interest compounded annually,* amount to the cost, less salvage, of the unit at the time when it reaches the end of its estimated service life. In applying this method, it has been common practice to compute annuities upon a basis of original or reproduction cost and total service life, but the method applies as well if, at any time, actual value and remaining service life are used.

3.—Compound-Interest Method.—(The same as the *Equal-Annual-Payment Method* discussed in the Committee's Progress Report.) This method makes provision from the earnings for annual depreciation allowances, for any property unit, of such increasing sizes from the beginning to the end of its estimated service life that when the same interest rate is used for determining the return on capital and the depreciation allowances, the sum of the return and the allowance is the same in each year of such life. The rate of increase of the successive depreciation allowances is also such that the "present worth" of each is the same. The sum of the allowances *without interest* equals the cost, less salvage, of each unit when it reaches the end of its estimated service life.

4.—Straight-Line Method.—This method makes provision from the earnings for equal annual depreciation allowances of such size, for any property unit, that the sum of the allowances, *without interest,* will equal the cost, less salvage, of each unit when it reaches the end of its estimated service life. The annual depreciation allowances by this method are each equal to the cost, less salvage, of the property unit divided by the number of years of its expectation of life.

5.—Unit-Cost Method.—This method is based on the conception that the value of a plant unit should be decreased from year to year to such an extent that the cost per unit of output or service, taking into account all annual charges for interest, depreciation, repairs, cost

of operating, etc., shall be constant during each year of the estimated service life of the unit.

Depreciation Allowance—Renewal Allowance—Retiring Allowance.

The provision which should be made through the rates by which a sum may be taken from earnings periodically for offsetting the decrease in value or worth of existing plant units. In accordance with methods of accounting in general use by railroads for a part of their property, and by some other public service corporations, the annual decrease in value or worth is offset wholly or in part by charges to maintenance or renewal expenses.

Depreciation Fund—Renewal Fund.

A fund consisting of cash or other quick assets set aside for the purpose of renewing property subject to depreciation when it ceases to be serviceable. This fund appears in the asset column of a financial statement, and may have no direct relation to the depreciation reserve.

Depreciation Reserve—Retiring Reserve.

The excess of past charges to "operating expenses" for depreciation which have been credited to the depreciation reserve account, over and above those retirements which have been charged thereto.

Deterioration.

Under DEPRECIATION.

Development Expense.

A term which may be applied to all expenses incurred in developing a property. In this report, however, it is limited to the expenses incurred in developing the property and business after the period of regular operation begins. That portion of development expense incurred in tuning up the plant and bringing the property to present operating efficiency during the physical development period may be accounted for as a construction cost. To a large extent, development expense represents the deficiency in net distributable earnings below a "fair return" on the "fair value" of the property during the early period of operation after original construction, and after important betterment or reconstruction. In other words, it is the cost of creating the business.

Development Period—Physical.

See PHYSICAL DEVELOPMENT PERIOD.

Duplication Cost.

See *Cost of Reproduction,* under COST—INVESTMENT.

Equal-Annual-Payment Method.

Under DEPRECIATION ACCOUNTING.

Exchange Value.

Under VALUE.

Expectation of Life—Life Term.

These terms mean the estimated economically useful life of the different units or different groups of units of which a property is composed.

Age.—The length of time that the property unit has been in use. Sometimes referred to as past life.

Remaining Life—Remaining Service Life.—Generally, the difference between the age and the total expectation of life of a property unit; but, as the unit grows older, the estimate of remaining service life, sometimes termed future life, may be changed by the condition of the property at the time of its appraisal.

Expense—Development.

See DEVELOPMENT EXPENSE.

Expenses—Operating.

See OPERATING EXPENSES.

Fair Return.

This term is used to indicate the return to which the owner of a public utility is equitably entitled for the use of his capital, in view of the risks involved and the efficiency displayed in management.

Fair Value.

Under VALUE.

Franchise.

The authority granted by government to a person or corporation to create and operate a public service property, to use public property, and often to condemn property.

Going Value—Going Concern Value.

These terms have been given many definitions. Mr. Justice Moody, in the Knoxville case, referring to an allowance for the going concern, makes this statement:

"The latter sum, we understand to be an expression of the added value of the plant as a whole, over the sum of the values of its component parts, which is attached to it because it is in active and successful operation and earning a revenue."

The term "going value" has also been given a less comprehensive meaning, in the valuation of public service properties, making it correspond closely with what has been defined heretofore as "development expense"; for instance, Judge Miller, in the Kings County Lighting case, said:

"I define 'going value' for rate purposes as involved in this case to be the amount equal to the deficiency of net earnings below a fair

return on the actual investment due solely to the time and expenditure reasonably necessary and proper to the development of the business and property to its present stage, and not comprised in the valuation of the physical property."

The Committee defines the term as the difference between the exchange value and the physical value of an established and operating property, due to the *intangible* values—such as franchise, good will, efficiency, favorable business arrangements, designs, strategic location, leases, easements, traffic and operating agreements, water rights, strategic advantages, and other rights or privileges—in contradistinction and addition to the development expense (or *tangible* costs and losses of the business-acquisition, or development-period, which are to be included in the physical value of the property).

Good Will.

In ordinary business, the good will represents the special value that a business has by reason of its popularity and the amount of business thereby attracted. It is a part of the value of a "going concern".

Improvements.

Additions and betterments to an existing property.

Inadequacy.

Under DEPRECIATION.

Increment.

See APPRECIATION.

Intangible Value.

Under VALUE.

Inventory.

The schedule with items multiplied by appropriate prices.

Investment.

See COST—INVESTMENT.

Item.

Under UNIT.

Items—Measurable.

See *Measurable Items,* under UNIT.

Life—Remaining.

See *Remaining Life,* under EXPECTATION OF LIFE.

Life Term.

See EXPECTATION OF LIFE.

Maintenance.

The act of keeping a property in condition to perform adequately and efficiently the service for which it is used. The term may be applied either to the property units which are kept in such serviceable

condition by repairs or otherwise, or to the property as a whole which may be kept in such condition by the replacement of parts which become worn or otherwise inefficient.

Under the rules prescribed by the Interstate Commerce Commission for steam roads, the word "maintenance" has a broader significance, as maintenance expenses include:

"also the loss through depreciation of the property used in operations, including all such expenses resulting from ordinary wear and tear of service, exposure to the elements, inadequacy, obsolescence, or other depreciation, or from accident, fire, flood, or other casualty."

Maintenance—Deferred.

See DEFERRED MAINTENANCE.

Market Value.

Under VALUE.

Measurable Items.

Under UNIT.

Obsolescence.

Under DEPRECIATION.

Operating Expenses.

Strictly speaking, these are the expenses incurred in operating a property, for which its owner is entitled to receive reimbursement through sufficiently large earnings. In accounting, the term has been given a broader meaning to include all expenses necessary for the maintenance of the integrity of the property and its operation.

Original Cost—Original Cost to Date—Original Cost plus Improvements.

Under COST—INVESTMENT.

Overhead Charges.

This is a term used for expenses incurred in producing a property, which cannot well be included in the unit prices. The methods of accounting used in connection with the construction of public or public service works do not, as a rule, provide for the charging of such expenses as those for promotion, administration, engineering, interest, and many other things to the different property units, although they are necessarily a part of the cost of such units. In the preparation of estimates of cost provision must be made, also, for contingencies which experience has shown do arise during construction. Hence, the engineer, using all available accounts and records as a basis, can make the most accurate estimate of reproduction cost by applying unit prices which do not include these overhead charges, and adding for the different elements which make up the overhead charges such percentages of the total cost of the plant units or measurable items of property, otherwise obtained, as are warranted by experience.

Physical Development Period.

The period, following the construction period, necessary to bring any physical property to present operating efficiency.

Physical Value.

Under VALUE.

Plant Unit.

See UNIT.

Prices.

See UNIT PRICES.

Property.

See PUBLIC SERVICE PROPERTY.

Property Unit.

See UNIT.

Public Purchase Base.

Under VALUE.

Public Service Commission.

The general title given to a public body authorized by law to regulate or control the actions of individuals, corporations, or public bodies owning or operating public utilities. As a rule, the authority is conferred on special bodies, as, for example, the Interstate Commerce Commission, and the public service commissions which have been created in recent years in most of the States, but this authority may also be conferred on the governing bodies of cities, as, for instance, in California, where, by the provisions of the Constitution of the State, the supervisors of a city were until recently required each year to fix the rates for water supplied by public service corporations to such city and its inhabitants.

Public Service Property—Public Utility.

The popular names given to a property created, under the provisions of a general or special law, to furnish service to the public. The public utility may be owned or controlled by individuals, a corporation, or a public body.

Public Utility.

See PUBLIC SERVICE PROPERTY.

Rating Base.

See *Return Base* under VALUE.

Remaining or Depreciated Value.

Under VALUE.

Renewal—Renewal in Kind—Replacement.

Renewal.—The making new of plant units by replacing them with corresponding new units, although the term is sometimes used even when the new units are not altogether similar to those replaced.

Renewal in Kind.—Used to indicate that the renewal is made with an identical plant unit.

Replacement.—The act of replacing a plant unit which is going out of service, with a substitute which may be either identical with the unit replaced or different from it. A replacement which increases the value is classed as an improvement to the extent of its increased cost.

Renewal Allowance.

See DEPRECIATION ALLOWANCE.

Renewal Fund.

See DEPRECIATION FUND.

Renewal in Kind.

Under RENEWAL.

Repairs.

The process of mending or of restoring to a sound and good state. In connection with the valuation of a public service property, the word may have two very different meanings. It may mean either the mending and restoring of parts of a unit to keep it in a sound and good state, or the mending and restoring of the defective parts of the whole plant to maintain it in a sound and good state. The meaning intended is sometimes indicated by the context, and where not so indicated the difference in meaning is a source of misunderstanding.

The frequently used term *current repairs* refers to the repairs belonging to the time immediately passing, and, like the word repairs, may relate either to plant units or to the whole plant.

Replacement.

Under RENEWAL.

Replacement Cost.

See *Cost of Reproduction*, under COST—INVESTMENT.

Replacement Method.

Scrap Value.

See *Salvage or Scrap Value,* under VALUE.

Service Life.

See EXPECTATION OF LIFE.

Sinking Fund—Amortization Fund.

A fund instituted and invested in such wise that its gradual accumulations will enable it to meet and wipe out a liability or debt at maturity. The term "sinking fund" is sometimes used loosely in connection with any kind of a fund which will reach the amount of a liability or debt at maturity, but should be used only in connection with a fund made up of annual or other instalments *which require the accumulation of interest* in order to reach the full value at maturity.

Sinking-Fund Method.

Straight-Line Method.

Under DEPRECIATION ACCOUNTING.

Supersession.

Under DEPRECIATION.

Taxing Base.

Under VALUE.

Unit.

A subdivision of a plant or property consisting of a single article or item, or a group of articles or items. The subdivision of the plant or property into units, not necessarily the same for different purposes, for convenience in estimating cost or in estimating and placing depreciation. A *plant unit* is a subdivision of the *physical property*; a *property unit* a subdivision of either *physical* or *intangible* property.

The term *plant unit* generally relates to a complete unit like a locomotive, a building, or a dam, and not to the parts like the wheels of a locomotive, the windows of a building, or the earthwork or masonry of a dam.

The word unit may be at times synonymous with the word item, but frequently will include two or more similar or dissimilar items. For instance, a dam may be called a property unit, but, in estimating its cost of reproduction, its various parts, such as earthwork, masonry, paving, etc., would be entered as items in the schedule. On the other hand, an item in a summarized schedule often includes many units.

Item.—An article; also a separate article or entry in an account or schedule.

Measurable Items.—Items of physical property which can be counted or measured.

Unit-Cost Method.

Under DEPRECIATION ACCOUNTING.

Unit Prices.

These are the prices or costs to be set opposite each plant unit of the schedule, as multipliers.

Valuation.

The general definition is the act of valuing. In connection with public service property, the word means the determination of actual or reproduction cost, depreciation, and the many other factors which affect "fair value" or the bases for estimating "fair return", permissible capital, public purchase price, or proper taxation and the determination of such "fair value" or bases.

Value.

Primarily defined in the Standard Dictionary as "the desirability or worth of a thing as compared with the desirability of something else". As the desirability or worth of a thing is usually estimated in money, this definition in the present case may be abbreviated to "the desirability or worth of a thing, estimated in money".

As indicated in the introductory chapter, the Committee is of the opinion that the confusion which has resulted from the use of the word, value, because of the many different shades of meaning that have been given to the word, is so great as to justify a modified terminology. It therefore recommends:

(*a*) that the meaning to be attached to the word value be the primary meaning as defined in the first paragraph, except when it is necessary to use the words "value" and "fair value" with the meanings assigned to them by the Courts;

(*b*) that, in so far as the practice of valuation is concerned, the word should not be used, except as above stated, without proper modifying words to indicate what meaning is intended;

(*c*) that the principal purposes of valuation being to furnish a basis for a purchase or rental price, to obtain evidence as a guide for rate-making or the determination of the reasonableness of rates, to furnish a basis for authorization of capital, and to furnish a basis for taxation—these bases not being necessarily the same and not being the equivalent of value in every case—the use of the word value should be avoided and the propriety of the following terms recognized:

Capitalization Base.—The sum on which capital securities may be issued or authorized.

Public Purchase Base.—The price which should be paid in the case of the purchase of a public utility by the public.

Return Base.—The amount on which the public service company is entitled to earn a "fair return". This is what the Courts have termed the "fair value", in various rate cases.

Taxing Base.—The amount which should be subjected to taxation. Under the laws of some States, the basis to be used for taxation of property is not its value estimated in money by any ordinary rules, but a sum determined in accordance with such laws.

Exchange Value.—The desirability or worth of a thing, estimated in money. (See also VALUE and MARKET VALUE.)

Fair Value.—As applied to a public service property, this is a technical term used by the Courts to express a base for rate regulation, public purchase, capitalization, or other purpose, which is fairly obtained and fair to the parties affected.

Going Value.—See GOING VALUE—GOING CONCERN VALUE.

Intangible Value.—Existing value which is not represented by physical property and is not measurable by determinable cost. Intangible value exists by reason of franchise, grants, contract rights, location, market, age, strategic advantages, and efficiency, and possibly other elements that give a property value.

Market Value.—This term, applicable only to a property for which there is a well-established market, has been properly defined as the sum which a willing and intelligent buyer desiring such property would give for it to a willing, intelligent and solvent seller.

Physical Value.—The value of the physical property in contradistinction to that of the intangible property. Riggs,* referring to the "physical property" element of value, says:

"This consists of those things which are visible and tangible, capable of being inventoried, their cost of reproduction determined, their de-

* "The Valuation of Public Service Corporation Property", by Henry Earle Riggs, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXII, June, 1911, p. 18.

preciation measured, and without which the property would be unable to produce the commodity on the sale of which income depends. This physical property is considered as an operating entity, and not as a collection of inert and partly worn-out equipment, and, being so considered, carries, as part of the physical value, those costs and charges which are an inseparable part of the cost of construction but do not appear in the inventory of the completed property."

This definition of physical property is broader than that sometimes given, which excludes the overhead charges. The Committee agrees with this definition of Professor Riggs, as all costs required to create the physical property and put it in its full present condition of operating efficiency should be included in determining the physical value.

Remaining or Depreciated Value.—The value of a property after proper deduction has been made for depreciation.

Salvage or Scrap Value.—These terms are often used interchangeably, but a distinction may be made that *salvage* is the net value which an article possesses for further use for utility purposes other than that for which it was originally used, or as a second-hand article; and *scrap* is the net value of an article no longer useful for service.

Wear and Tear.

Under DEPRECIATION.

Weighted Average.

The average found by dividing the sum of the several products of a series of multiplications of variable factors, by the sum of the factors of one class.

Working Capital.

Under CAPITAL.

APPENDIX II.

Some Examples of the Expectation of Life of So-Called Permanent Structures.

When one examines records of the life of different kinds of so-called permanent structures, the actual life of such structures is frequently found to be much shorter than the life usually estimated, and probably much shorter than was anticipated when the works were new. For the purpose of illustration, this subject has been investigated along two lines: (*a*) the actual life of railway stations, and especially of terminal stations; (*b*) the life of water-works sources, reservoirs, and pumping stations.

TABLE 5.—Life of Railway Stations.

Location.	Year when built or enlarged.	Life, in years.	Remarks.
Grand Central Station and Predecessors, New York City.			
241 Bowery, at Prince Street	1832	7	
Tryon Row (Municipal Building)	1839		
Fourth Avenue and Twenty-sixth Street (Madison Square Garden)	1857	18	
Forty-second Street	1873	16	
Forty-second Street. Extensive enlargement	1884		
Forty-second Street Station. Entirely remodeled and three stories added for offices	1899	34	
Construction of new terminal started	1903		
Present station first used for electric service	1907		
Present station in full use	1912		
Boston and Albany Railroad, Albany, N. Y.			
Wooden building at Colonie and Broadway	1866	7	
Brick and stone building at Maiden Lane	1873		
Existing stone station	1900	27	
Boston and Albany Railroad, Boston, Mass.			
Original station	1834		History between these dates not known.
Kneeland Street Station	1881	18	
South Station (Union Station)	1899		
Boston and Providence Railroad, Boston, Mass.			
Original station	1834		History not known.
Park Square Station	1874	25	
South Station	1899		

TABLE 5.—LIFE OF RAILWAY STATIONS.—(*Continued.*)

Location.	Year when built or enlarged.	Life, in years.	Remarks.
NEW YORK AND NEW ENGLAND RAILROAD, BOSTON, MASS.			
Original station	1855	17	
Station burned and rebuilt	1872		
Station extensively remodeled	1880	27	
South Station	1899		
BOSTON AND MAINE RAILROAD, BOSTON, MASS.			
Haymarket Square Station	1846	47	
North Station (Union Station)	1893		
EASTERN RAILROAD, BOSTON, MASS.			
Causeway Street Station	1854	9	
Station burned and replaced by brick building	1863	30	
North Station	1893		
FITCHBURG RAILROAD, BOSTON, MASS.			
Causeway Street Station	1848	45	
North Station	1893		
BOSTON AND LOWELL RAILROAD, BOSTON, MASS.			
Minot Street Station	1835	17	
Causeway Street Station	1852		
Causeway Street Station rebuilt	1873	21	
Merged into North Station, with minor alterations	1893		
BOSTON AND ALBANY RAILROAD, WORCESTER, MASS.			
Original station	1835	36	History not known.
Union Station	1875		
New Union Station	1911		
Average life of all stations		24	

The Forty-second Street Station, in New York City, although credited with a total life of 34 years, had that length of life only for the part built in 1883. The extensive enlargement in 1884 had a life of 23 years and the remodeled station of 1899, had a life of but 8 years.

Life of Water-Works Structures.

The average life of the sources of water supply given in Table 6 was shortened by the introduction of a general system of water supply for the Metropolitan District, which made the further use of small local supplies undesirable.

Lake Cochituate, the original source of supply of Boston, has been in use 65 years, and the Sudbury River, the second source of supply of the city, has been in use 36 years, but both these sources are now used only to a limited extent to supplement, when necessary, the supply from the Wachusett Reservoir, the newest source.

TABLE 6.—Sources of Supply.
Massachusetts Metropolitan Water District.

Source.	Period. Years.	Life, in years.	Remarks.
Boston, Mystic Lake source, supplying 12 000 000 gal. daily in the last year of its life	1864-1898	34	Abandoned on account of increasing pollution.
Malden, Spot Pond	1870-1898	28	
Malden, ground-water source	1890-1900	10	
Quincy, ground-water source	1884-1898	14	
Quincy, storage reservoir	1888-1898	10	
Hyde Park, ground-water source, near Neponset River	1885-1912	27	
Hyde Park, ground-water source, near Mother Brook	1899-1912	13	
Medford, Spot Pond	1870-1898	28	
Medford, storage reservoir	1894-1899	5	
Revere, ground-water source in town	1884-1898	14	
Revere, ground-water source in Cliftondale	1891-1899	8	
Melrose, Spot Pond	1870-1898	28	
Watertown, ground-water source	1885-1898	13	
Arlington, storage reservoir	1872-1899	27	
Arlington, ground-water source	1895-1900	5	
Swampscott, ground-water source	1885-1899	14	
Lexington, ground-water source	1884-1903	19	
Lexington, storage reservoir	1894-1903	9	
Average		17	

Reservoirs.

At the time of the completion of the original works supplying Boston, in 1848, there was a reservoir of 23 acres in Brookline at the end of the brick aqueduct. The pipes from this reservoir led to three distributing reservoirs: one of them, on Beacon Hill in Boston, was a large elevated masonry reservoir supported by arches; the other two were earthen reservoirs on hills in South Boston and East Boston.

The Brookline Reservoir lost a large part of its value at the end of 22 years, when it was superseded by a larger reservoir, but it had a life of 52 years before its use was discontinued. The use of Beacon Hill Reservoir was discontinued in 23 years; of the South Boston

Reservoir in 24 years; and of the East Boston Reservoir, except for the purpose of emergency use, in 32 years.

As in the case of the sources of supply, the life of pumping stations in the Massachusetts Metropolitan Water District, has, in many cases, been shortened by the introduction of a general system of supply. The oldest of the five existing pumping stations in this district was built 26 years ago, and the building was extended 11 years after it was built.

A study of other water systems shows that sources, pumping stations, reservoirs and other works are frequently abandoned for various reasons, such as the pollution of sources, the growth of population at higher elevations than those originally provided for, and the general improvement and enlargement of the water system to meet changing conditions.

An instance of an extremely short life of a reservoir and pumping station was observed in connection with a valuation for rate-making made in 1909. The rates in question were those of 1904 and 1905. The pumping station and reservoir did not appear on the inventory for 1904, because they had not then been built. They did appear on the inventory for 1905, but could not be seen by the appraiser in 1909 because they had been superseded and removed. The cause of the short life was a great influx of population which settled on elevated land and required a more complete system of high-service works.

TABLE 7.—PUMPING STATIONS.

	Period. Years.	Life, in years.
Boston, original high service	1870-1888	18
Old East Boston	1880-1889	9
New East Boston	1889-1898	9

Hyde Park, Mother Brook Station	1899-1912	13
Medford, Spot Pond Station	1892-1898	6
Medford, Reservoir Station	1894-1899	5
Revere, Town Station	1884-1898	14
Revere, Cliftondale Station	1891-1899	8
Melrose	1886-1899	13
Watertown	1885-1898	13
Arlington	1895-1900	5
Swampscott	1885-1899	14
Lexington	1884-1903	19
Average		14

*This pumping engine was transferred to another pumping station when the Mystic Station was abandoned.

On the other hand it is not to be inferred from Table 6, that the average life of sources of water supply is but 17 years, or from Table 7, that the average life of pumping stations is but 14 years—for the life history of the majority of water-works will show that such is not the case. These examples have been cited merely to indicate that functional depreciation is an active force to be considered and given such practical weight as circumstances and experience may indicate to be fair.

Thus, by comparison with Table 7, there might be cited the experience of the Spring Valley Water Company, of San Francisco, Cal. Out of eight pumping stations (excluding the centrifugal booster and ground-water supply stations, recently erected and still in service), all but one are in active service—and this one was an emergency station, and not one of permanent construction. The age of the oldest station is about 30 years, the mean age of the investment in the eight stations, 15 years.

Table 8 is a statement of the pumps in these stations.

TABLE 8.

Fly-wheel pumps.		Direct-acting pumps.	
Black Point	1-30 years.	Ocean View	2-18 years.
" "	2-22 "	Precita	1-17 "
Belmont	2-28 "	"	1- 8 "
"	3-15 "		
Merced	2-25 "	Centrifugal pumps.	
Millbrae	1-18 "	Ravenswood	1- 4 years.
Central	1-18 "	Pleasanton	1- 3 "
Clarendon	1-15 "	"	1- 7 "
		Crystal Springs	3- 3 "

No pumps have been discarded, except three small double-acting low-duty pumps at Bald Hill emergency station, used in two or three dry years for a few months only.

This comparison is made merely to indicate that each problem must be thoroughly studied in the light of the local past, present, and probable future conditions.

APPENDIX III.

Some Examples of Actual Overhead Cost.

In presenting these data as to actual overhead cost, the Committee desires to lay stress on the need of using all such figures with caution. Items entering into overhead cost of different and similar works are rarely alike, and many of the expenses, and even classes of expense, incurred on one piece of work, might not be incurred on another. It is impossible to forecast all the conditions and items of overhead cost which will develop on any work. Were it otherwise, no separate group of overhead cost would be necessary, for every expense would be included in the unit costs.

Experience has shown, however, that indeterminate or indeterminable expenses always occur, and in such amount that they frequently aggregate like, or similar, percentages of fixed unit costs. Hence, the mere amount of those percentages, developed on other works, has a bearing on the problem. Their segregation aids in forecasting probable developments the more accurately, and they furnish a background of comparative experience which is useful.

Moreover, in valuing properties, years after their construction, grave uncertainties generally arise as to the conditions which actually developed during the construction of these works, and records are virtually never in sufficient detail to eliminate them. Therefore, the evaluator, as the designing and constructing engineer, must make reasonable allowance, to cover the effect of these uncertainties, if justice is to be done.

To the evaluator, the records of greatest value are those developed on work, with all the details, conditions, and surroundings of which he is personally familiar, as these he is in a position to use most intelligently as a yard-stick, and is least likely to misapply. The evaluator should not attempt to figure the value of property with the construction costs of which he is not familiar.

With reference to the data submitted, the details presented to the Committee were so voluminous as to be impracticable of publication.

* G. P. Cutten, Esq., Counsel to the Company, who furnished these records, writes (August 14th, 1915): "It must be borne in mind that the construction costs in this table are actual costs taken from the books, and all contingencies, etc., which occurred on the jobs are in the unit costs. An evaluator must make separate allowance for these contingencies in his overhead, which would increase the overhead on a comparative basis from 5 to 10 per cent."

(c).—Examples of Overhead Costs on Various Works.—(*Continued*).

* Includes 1% allowance for lost interest on cash balances and difference between interest paid and that received on reinvestments. F. P. Stearns thinks this an over-estimate and that it may have been as low as 0.5 per cent.

† Interest to date of active use of structure (before completion).

‡ It is to be noted that on the Metropolitan Water Board an appropriation of $27 000 000 was made available in the Metropolitan Water Act at the inception of the work in 1895. This, coupled with the State Treasurer's ability to keep most of the idle funds of the State invested in temporary loans to municipalities within the State at practically equal rates of interest, made it possible for the Board to sell its bonds virtually as the demand for construction funds accrued, without the loss in interest usually resulting from having to sell the securities at one time, and to reinvest the surplus funds in readily convertible loans at the best possible interest rate—practically always lower than the rate obtained on the bonds, until needed. Mr. Frederic P. Stearns states that, as a result of these conditions, the interest during construction was extremely low—probably without parallel.

(e).—Interest During Construction.—(*Continued*).

(2).—Cases Presented to Interstate Commerce Commission in Argument and Brief, September 1st, 1915.

Name.	State.	Miles.	Percentage.
Kansas City Southern	Missouri	3.4	2.6
Chicago and Northwestern	Wisconsin	178.0	2.8
Illinois Central	Kentucky	32.0	1.3
Sunset Central	Texas	47.0	2.8
Union Pacific	Nebraska	26.0	2.5
Southern Pacific	California	143.0	2.5

"The total investment for these 4 390 miles of western lines was $126 711 214, exclusive of land, equipment, and overhead charge; the charge to engineering was $5 193 116, the construction cost per mile being less than $29 000.

"The East reports 42 cases (exclusive of the Pennsylvania Tunnel and Terminal Company and the New York Central developments in New York). The mileage covered is 817 miles, or but 19% of the length reported by the West, the total investment, excluding land, equipment, and overhead, being $132 528 399, or $5 817 185 more than the 4 390 miles reported by the western lines.

"The engineering cost for these 817 miles was $7 677 089, or 5.79%, an increase in rate of 41% over the western lines. The average cost per mile was $162 239, or 5.6 times the amount per mile expended on the western roads reporting."

Name.	State.	Miles.	Percentage.
Boston and Maine	New Hampshire	7.5	1.7
Pennsylvania Lines West	.....	6.0	2.2
Western Maryland	.....	86.0	2.6
Delaware and Hudson	.....	14.0	2.2

Chicago and Eastern Illinois	Illinois	62.0	1.8
Chicago and Eastern Illinois	Illinois	63.0	2.6

"The New York Central and Hudson River Railroad Company, the Barge Canal, and five cities spent $256 800 000 (including land), of which $133 000 000 was expended outside the City of New York. The engineering expense on this work that was charged amounted to 7.6% on all items of construction, including land.

"The Pennsylvania Tunnel and Terminal Company, with 11.81 miles of first track and 69.42 miles in all, cost $111 701 889, exclusive of equipment, taxes, interest, or overhead charges other than engineering; of which amount, $20 679 950 was for land, or 18.5% of the total. The charged cost of engineering was 7.2% of the cost, excluding land and equipment.

"The South reports 30 cases, covering 1 638 miles, with an investment, including land, but excluding equipment and overhead, of $78 546 665. The charged cost of engineering on these 1 638 miles was $3 492 248, or 4.4%, including land."

(*g*).—LAND.—OVERHEAD CHARGES.—STATEMENTS SHOWING SOME EXPENSES OF RAILROAD COMPANIES IN THE ACQUISITION OF LAND.

Statement of Thomas W. Hulme, General Secretary, Presidents' Conference Committee, at Conference between Division of Valuation, Members of State Commissions, and Representatives of the Presidents' Conference Committee of the Railroads, May 28th, 1915.

Owning company.	Acquired for:	Total purchase price, exclusive of expense of acquisition.	Expense of acquisition.	Percentage of purchase price.	Remarks.
Baltimore and Ohio Railroad	Produce yard, Baltimore, Md.	$206 724	$10 186	4.90%	Expense ratio as to property purchased, 3½ per cent. Expense ratio as to property condemned, 16.7 per cent.
Bessemer and Lake Erie Railroad	Kremis to Osgood, Pa. (K. O. Line)	63 211	3 299	5.22	$342.96 included in purchase price would more properly be included in expense; and *vice versa* as to $892.56.
Boston and Maine Railroad	Mechanicsville, N. Y., transfer yard	28 185	336	1.30	To cover salaries, $500 has been used.
	Newport, Vt., freight yard	18 450	812	4.40	
	Salem, Mass., freight yard	6 920	554	8.0	
Chesapeake and Ohio Railroad	Guyandotte Valley Extension, W. Va	28 400	1 848	6.51	
	Buffalo Creek Branch, W. Va.	44 095	1 925	4.37	
	Big Sandy Branch Extension, Ky.	236 953	25 091	10.59	Acquired in 1902.
	Coal River Branch, W. Va.	43 931	2 355	5.36	
	Yard at Peru, Ind.	11 850	964	8.14	Much negotiation required.
	Gravel pit near Peru, Ind.	9 970	612	6.14	
	Terminal purposes at East End, Binghamton, N. Y.	282 129	4 775	1.69	
Delaware and Hudson	Delanson to Schenectady, N. Y.	212 195	32 498	15.25	Of this ratio 12.46% represents expenses incurred in condemnation proceedings.
	Terminal purposes at Schenectady, N. Y.	346 750	8 896	2.56	
	Yard and cold storage plant, Glenville, N. Y.	83 100	1 710	2.06	
	Totals carried forward	$1 622 863	$95 861		

(*g*).—LAND.—OVERHEAD CHARGES.—STATEMENTS SHOWING SOME EXPENSES OF RAILROAD COMPANIES IN THE ACQUISITION OF LAND.—(*Continued*).

Owning company.	Acquired for:	Total purchase price, exclusive of expense of acquisition.	Expense of acquisition.	Percentage of purchase price.	Remarks.
	Brought forward	$6 321 910	$354 797		
Pennsylvania Railroad	Darby Creek Line	1 522 400	73 610	4.84	Of the 4.84% representing expense of acquisition, 1% engineering expense on account of surveys on present and former locations.
Philadelphia, Baltimore and Washington Railroad (Pennsylvania Railroad Company.)	Glynden to Lovell	62 896	6 658	10.53	The large number of properties, and widely scattered ownership, made it necessary to consume much time in traveling.
	Additional tracks, Newport to Pencader, Del	32 205	3 687	11.45	Difficult negotiations and widely scattered ownership, taken in connection with the small total purchase price, made the expense ratio rather high.
Pomeroy Belt Railway (Hocking Valley Railway Company.)	Extension near Pomeroy, Ohio	14 317	926	6.47	
Quemahoning Branch Railroad (Baltimore and Ohio Railroad Company.)	Husband line	56 750	3 464	6.10	In the purchase price, as given, are included $4 859 paid for damages to crops, change of roads, privilege of wasting material, etc. If this amount be excluded from the purchase price, the expense ratio will be 6.60 per cent.
Vandalia (Pennsylvania Railroad West.)	Harmony to Terre Haute, Ind	112 756	4 390	3.89	
	Eagle Creek Connection, Ind	26 013	1 596	6.13	
Winston-Salem South Bound Railway Company (Atlantic Coast Line.)	Tar Branch Terminal Line	240 483	3 558	1.48	The figures submitted show an expense ratio of 1.73%, based on a total purchase price of $205 299. The accompanying statement, however, shows that the purchase price should be $240 483. Hence the ratio of 1.48 per cent.
	Totals	$8 389 730	$452 656	5.4%	

(*h*).—Analysis of Certain Land Purchasers by Railroads.

Details of passenger coach yard purchase, St. Paul.

There were no condemnations, all tracts being bought at private sale.

There were no severance damages, the entire tract being bought in each case.

The law requires the Tax Commission to determine ratio of assumed valuation to real value, and the "assessment method" is based on actual assessment affected by this ratio.

	Before the identity of the purchaser was known.	After the identity of the purchaser was known.
Area purchased	581 120 sq. ft.	388 931 sq. ft.
Total purchase price	$94 000.00	$269 700
Deduct amount paid for improvements	11 083.33	69 132
Amount paid for land	$82 916.67	$200 568
Price per square foot paid for naked land	0.143	0.558
Total naked land value determined by assessment method	44 535.00	49 536
Naked land value, assessment method, per square foot	0.077	0.138
Excess paid over value by the assessment method	$38 381.67	$151 032

Summarized, the above figures show:

Naked land value determined by assessment method.	$94 071.00	23%
Paid for improvements	128 023.47	31%
Paid, in excess of value, by assessment method	189 413.66	46%
Paid for severance damages	0	0
Expenses of acquisition	$411 508.13	100%

The actual expense of the Right-of-Way Department was $3 553.20, or only 0.86% of the total purchase price. There were 21 parcels acquired and two others secured by exchange of site and removal of buildings, making 23 owners dealt with. Expense per parcel, $154.50.

Details of Knife River Branch, N. Dak., Northern Pacific Railway.

	Mercer Co., N. Dak.	Dunn Co., N. Dak.
Valuation of naked land, made by real estate men and bankers, not by employees. Per acre	$22.07	$22.13
Total	$15 769.42	$12 065.12
Total number of deeds	86	63
Total acres conveyed	784.97	615.55
Average acres per transfer	9.12	9.77
Total consideration	27 460.	17 106.
Average consideration per acre	35.00	27.80
Total number of considerations	4	None
Acres condemned	70.83	.....
Award in condemnation cases	1 966.52	.....
Average per acre, award	27.70	.....

Summary.—Both Counties.

Total naked land value	$27 774.54	62.32%
All other elements of value	16 791.89	37.68%
Total purchase price	$44 566.43	100%
Expense of acquisition	9 258.79	
Ratio of expense of acquisition to purchase price	20.77	

Expenses of Acquisition.

	Total.	Average per deed.	Average per acre.
Services and expenses of right-of-way agents	$6 790.75	$46.19	$4.85
Services and expenses of attorneys	705.69	4.80	0.50
Cost of abstracts and opinions of title	1 227.80	8.35	0.93
Cost of recording deeds	329.55	2.24	0.23
Automobile hire	205.00	1.40	0.15
	$9 258.79	$62.98	$6.66

This case affords an illustration of the extremely favorable cost of acquisition. The line was desired by the people. There was but little contest. Two of the condemnation cases were to acquire land owned by the State of North Dakota, the other two were against land companies. Every individual owner was settled with, yet, in spite of these facts, the land cost was $27 774.54, and "other elements" plus cost of acquiring amounted to $26 050.68, or 93.8% of the bare land price.

Details of Bear Creek Branch, Northern Pacific Railway.

The Bear Creek Branch, built in an irrigated valley under high cultivation, paralleling within 2 miles an existing road, was not desired by the farmers.

The assessed value, based on sales of 5 916 acres in 1913-14, was 25.3% of sales. On this the assessor's statement that 25% is a fair average is accepted for part of the district, but 20% was used on part.

Condemnation occurred in seven cases, in each case the award was divided into (*a*) actual value of strip taken, (*b*) damages to remainder.

Area taken by condemnation	23.57 acres	
Award for strips taken	$3 624.00	13.2%
Award for damages	23 930.00	86.8%
Total award	$27 554.00	100%

It is to be noted that the award for strips averaged $153.75 per acre, as against an actual land value, based on assessment method and opinion, of $59.85 per acre plus $20.00 for growing crops. This award was $73.90 in excess of actual value.

The total purchases were as follows:

Bridger to Belfry	155.78 acres at $59.85	$9 323.43	
Belfry to Bear Creek	104.26 " " 25.15	2 622.06	
	260.04 "		
Bear Creek town lots		2 206.08	
Total naked land value		$14 151.65	12.33%
All other elements of value		100 606.60	87.67%
		$114 758.28	100.00%
Expense of acquisition		$5 384.35	
Ratio of expense of acquisition to total purchase price		4.7%	

Details of costs of acquisition, 56 parcels, 260 acres plus 59 town lots.

	Total.	Per parcel.	Per acre.*
Abstracts of title	$725.25	$12.95	$2.70
Recording deeds	111.40	2.00	0.41

Investigations of the California Commission.

In the proceedings to determine the valuation of the Petaluma and Santa Rosa Railway, the finding was written by Commissioner Shelen. In his discussion of right of way, he states (Decision No. 2348—Case No. 145—Publ. Serv. Reports, 1915 C 752):

"The records of the engineering department contain the analysis of some 1 140 miles of recently constructed railroad rights of way in California, the total cost of which is $8 211 632.65, and the market value of the land for ordinary purposes, at the time of purchase, was $6 293 862.89, which would show a multiple of 1.30. The incidental expense in connection with the acquisition of 844 miles of this right of way was $648 329, which is 9.14% of the amount paid to the grantors. Practically 88% of the costs of lands was for property located within incorporated city limits, and the multiple on this classification was approximately 1.25."

APPENDIX IV.

Records of Abandoned Property.

The Committee calls the attention of engineers and administrators of public utility properties to the desirability of keeping as clear and complete a record as possible of the property abandoned by the corporation, annually and in aggregate amount.

Such records will be of great service to Courts and commissions, in assisting them to determine the annual depreciation allowance which should fairly be made for any public utility property, in the light of its past history, as well as of an intelligent forecast of its probable future.

It is obvious that such records—when used as a check on, or when coupled with, an estimate of the accrued depreciation on the existing property—will reduce substantially the element of uncertainty which must attend all such computations, based, as they must always be, on probable future, as well as on past, conditions.

As an example of such records within the water-works field, and of their applicability, the following table is cited, embodying the results of a continuous effort to collect such data, during a period of 15 years, more or less, on the part of Allen Hazen and Leonard Metcalf, Members, Am. Soc. C. E.

It seems highly probable that, by keeping such records in detail, there will be developed, in the course of time, sufficient information to admit of the setting aside of the fair annual depreciation allowance on a basis of percentage-of-gross-revenue of the operating company, a method which would have much advantage, on account of its simplicity of accounting, as well as for other reasons.

Inasmuch as this table is submitted for suggestive purposes only, and not for direct application, it is unnecessary to record here a description of the various plants, or the methods of determining the figures contained in the record, though it may be added that these figures have been taken in large measure from authoritative sources, such as Court, commission, or agreed, findings.

Depreciation Records of Some Old Water-Works.

Assembled and Analyzed by Allen Hazen and Leonard Metcalf, Members, Am. Soc. C. E., December, 1917.

DISCUSSION

Mr. Willoughby.

J. E. WILLOUGHBY,* M. AM. SOC. C. E. (by letter).—In its conclusions on the Fundamental Principles of Valuation, the Committee fails to direct especial attention to the fact that the principles and methods must be such as will insure to a property subject to competition an opportunity to benefit in what is sometimes called the unearned increment, in order to attract capital to the service of the public. The investor in a railroad property must have a hope of gain beyond the current rate of interest, because there can never be a guaranty that a railway (as it is always subject to competition) will earn the current rate of interest on its "fair value".

The Committee's classification of "New Properties", "Old Properties under Continuous Regulation", and "Old Properties not Under Continuous Regulation", leads to the assumption that the Committee considers the fair value of the property to be related in some way to past accounting. Such a conclusion is unfortunate. The fair value of a property is not affected in any way by the accuracy or inaccuracy of the accounting. The book record only, of the cost of a property, is thus affected. Even if the capital expenditure accounting were correctly kept throughout the history of a property, the accounting would show merely the monies expended on it, less retirements, and the accrued depreciation, if any, and the accumulated assets. The accounting will not show the fair value of the property.

The writer is not in sympathy with the idea that a property has one value for rate-making purposes, another value for capitalization, and yet another for taxation. It is quite true that property of all kinds is returned for taxation at less than its market value. Some States—*e. g.*, Alabama—fix by statute what percentage of the market value shall be subject to tax levy; in other States, such a percentage is fixed by common consent. It is also true that it will be imprudent for the operating management of a steam railway property to capitalize many items of expenditure which the Interstate Commerce Commission Accounting Classification permits—*e. g.*, the assessment against the railway for a sewer—because the expenditure, being in the nature of a tax, ought to be provided for out of income. Only those expenditures should be capitalized by the operating management as may increase the revenues of the railway; as may lessen the operating expenses; or as may be conducive in some measure to the safety, comfort, or convenience of the employees or patrons of the railway. The rates fixed by and for the railway should be sufficient to provide for expenditures out of income to cover all expenditures which do not come within this classification.

* Wilmington, N. C.

Mr. Willoughby.

The exception which the Committee makes in its list of "Physical Property to be Included in Valuation" (page 1319) under *"Excessive Size or Capacity"* is not consistent. The Committee correctly proposes to value the actual property as existing on the day of valuation, and not a substitute property serving the same purpose. The Committee should not vest the engineer in charge of the valuation with the power of reviewing the errors of judgment of the original construction, because that is but a step toward valuing the theoretical property, which will serve the same purpose, and is abhorrent to the Committee's views. Under the exception, much of the present railway construction will be eliminated in part from a valuation. There are noteworthy examples in the Union Passenger Station at Washington, the Pennsylvania Terminal in New York City; and in abnormal expenditures for low grades and multiple tracks in some recent railway construction.

The writer will add, as a corollary to the paragraph "Title to Property not Conclusive", that all structures on land to which the owner of the public utility has title should be included in the valuation. The inventory of land will necessarily include all lands to which the owner has paper title, and not held adversely by others; and also all lands which the owner holds adversely to others, the owner being without paper title. The theory of the law, that ownership of land covers ownership of all fixed improvements, gives to the railway owning the land all fixed improvements thereon, although those improvements may have been paid for wholly or in part by others. This view is not inconsistent with the theory of cost of reproduction which requires us to consider the railway under investigation as the junior line. Deeds to lands and the possession of lands in absence of deeds are the physical items of an inventory of lands, just as the cross-ties, rails, and fastenings are physical items of an inventory of track. In an estimate of cost of reproduction, all structures and appliances that exist to enable the railway under investigation (called *A*) to cross another railway (called *B*) must necessarily be inventoried in favor of the railway *A*, regardless of ownership of land, because such expenditures are a part of the cost of crossing. The railway *A*, under investigation, being nonexistent, must provide such structures and appliances as will enable railway *A* to surmount the physical obstacle which exists as railway *B*. In like manner, when railway *B* is under investigation, the cost of structures and appliances to cross railway *A* must be inventoried in favor of railway *B*. This double inventory is not contrary to the public interest, because the public benefits enormously in the reduction of unit costs from the assumption of the existence of all railways except the railway under investigation, and suffers only a very small addition to the collective estimate of cost of reproduction of all the railways. The writer has noticed with impatience the recent discussion of methods for dividing the cost of crossing structures between the two railways

Mr. Willoughby.

on some historical basis, because such discussion contemplates merely a way to prevent the assessment twice of a very small item of the cost of reproduction, and at the same time to lessen greatly the actual historical costs of the property under investigation in all items that the presence of the railway to be crossed will affect.

The Committee is correct in its conclusion on "Cost of Reproduction" (page 1321) that the identical property is to be reproduced, and not a substitute, and that normal present conditions shall determine the prices and methods for doing the work. It is worth while to review just what these conclusions require for railway valuation:

1.—The rail and fastenings, ties, ballast, and track accessories must be considered as new, and of the quality inventoried. It is true that many branch lines of the greater systems were laid with relay rail on the date of first construction, but such practice was a result of the development of the system. It will be inconvenient to go into this feature of development expense—*i. e.*, to assess the losses to the railway due to the removal of rail from principal lines, before the full life of the rail had been obtained, so that relay rail for branches might be available. Considerable quantities of relay rail are not sold in the market for new construction, and therefore it is inconsistent with the theory of reproduction to estimate relay rails for branch lines when the material is not available for purchase for such works. By assessing the decretion to the rail fastenings and track accessories in branch lines, from new to the date of inventory condition, the interest of the public will be fully protected. Many sections of the country are without suitable ballast, and ballast is necessarily handled for long distances, over tracks that have been surfaced on a temporary ballast. A haul is now being made, on gravel ballast to points in Florida, that averages 490 miles. The unit costs must cover the haul. The construction programme will provide properly for the use of temporary ballast, and the hauling and placing of the permanent ballast after completion of the track laying, but the time limit for construction must be greatly extended, and special equipment must be provided for. It will be improper to consider that the entire energies of the railway will be exerted in hauling ballast. The ballast movement will be subject to the delays of the railway's date of valuation traffic—that traffic being one of the present-day conditions.

2.—The cuts and fills must be of the dimensions and of the materials shown on the date of valuation. A fill made of rock or of clay in a sand country must be so inventoried, regard-

Mr. Willoughby.

less of whether the adjoining country exhibits only sand. On many of the railways in the Atlantic Coastal Plain, where the soils are largely sand, clay has been hauled many miles, and at great cost, to aid in making a stable embankment. A cut that, at the date of the inventory, is too narrow for steam shovel operation must have unit prices affixed commensurate with the cost of removal by wagons, carts, scrapers, or hand, and must have a time limit sufficient for these slower methods. The cuts in Florida sand (which is too light to support teams) must be considered as being removed by hand (or by steam shovel if the dimensions warrant), and must have unit prices affixed on such basis. Where present-day construction methods still provide for the two-way basis of pay for earthwork, the two-way basis must be assumed. Embankments through the swamps of the Southeast, which will require trestles for construction, on account of lack of available borrow, must have that feature of cost considered. Especial attention must be given to inventory the condition of the material in the top surface of the roadway. All the older railways, by the tamping action of traffic, and by the provision of select soils for track surfacing in past years, have built up the roadbed into a dense crust, impervious to water, and of great sustaining power for the ballast. This crust is an asset to be inventoried. It is not usually obtained in present-day construction because ballast is put directly on the soft roadbed, with resulting water pockets and other objectionable features. A rock cut in a town or city must have unit prices large enough to cover the extra cost of taking the rock out so as not to injure persons and property adjoining, although the town or city may have been built up about the cut after the latter was actually excavated. Borrow from an embankment must be taken from points now available. The inventory must locate available borrow-pits. Borrow cannot be assumed as being taken from improved city property, although the borrow may have been originally obtained from the grading of vacant lots before the city was built.

3.—The bridges, trestles, and culverts must be of the dimensions and material shown on the date of inventory. Where stone, sand, and gravel for masonry is available in quantities necessary for the completion of the work within the adopted time limit only at great distances from the work, these materials must have unit prices sufficient to cover the cost of hauling from those distant points. Concrete is now being built on a new line in Central Florida, for which the gravel is hauled

Mr. Willoughby

600 miles, and for which sand is hauled 200 miles, because there is neither suitable gravel nor sand for concrete available in the territory through which the new line is being built.

4.—The right of way of the railway to be valued is cleared and usually grubbed. Proper consideration of these items requires that they shall be assessed on the basis of the condition of adjoining lands. If the adjoining lands be fields that are now cleared and grubbed, the assumption lies that the right of way will be cleared and grubbed, and *vice versa*.

5.—Due consideration must be given to the normal resources of the country as to labor and supervision. Labor is limited in amount, and any great increase in demand for labor causes the wages to rise and carries increased unit costs. The construction programme must not be shorter than the normal labor resources warrant.

6.—The annoyances, expenses, and delays of and to the conduct of construction works under present-day public antagonisms, political chicane, and legal proceedings must all be incorporated in the costs of reproduction.

The writer is not in accord with the Committee that "history must also be considered, to determine what is to be reproduced, the conditions under which it is to be reproduced, and how estimates must be made". History has no place in an estimate of the cost of reproduction of a railway, except in so far as history is reflected in the experience of the engineer who makes the valuation. In a railway, the items to be reproduced are capable of being inventoried to the extent that such items are now duly inventoried in the construction engineer's estimate in advance of actual construction of present-day works. The idea underlying cost of reproduction is to fix: For what money can the existing property be built now? To mix the past with the present will only confuse the issue.

In making a proper financial and construction programme, unlimited capital must not be assumed. All our large systems of railways have been built up slowly, and the capital required has been available generally on reasonable terms. The tendency of engineers in fixing a programme for reproduction is to consider the physical items only as affecting the time limit. Experience does not justify ignoring the effect which capital requirements will have on the time limit, the unit prices, and the total cost of the property.

There is a value due to continuity which attaches to a railway right of way, but this value is not to be considered in connection with the cost of reproduction. It must be considered as a part of the fair value of the property when that value is fixed.

Mr. Willoughby.

The writer expresses his approval of the distinction made by the Committee between "decretion" and "depreciation" (page 1324). For a railway, the Committee might have brought out more clearly the fact that decretion is an operating expense which for the older railways is taken care of by annual renewals, and which is invariably more than offset by assets of the railway other than those entering into a cost of reproduction valuation.

The Committee's conclusion on depreciation (page 1328) is a correct one. The words "funds held in reserve for such property", mean, of course, securities as well as cash.

It is well to remember that, in ascertaining the value of accrued depreciation, the basis is not the original cost of the item, but the replacement cost. As an example, the labor cost of track laying and surfacing on new lines varies from $1 000 to $2 000 per mile. The labor cost of relaying the rail and fastenings, chargeable also to track laying and surfacing under the Interstate Commerce Commission Classification, varies from $200 to $500 per mile. It is proper to apply decretion to track laying and surfacing, but only to the sum necessary to relay. In some of the tentative valuations of railways lately issued by the Interstate Commerce Commission, depreciation is applied to the cost of track laying and surfacing as of new lines, and the accrued depreciation so determined is in excess of the total cost of relaying, which means that the decretion is more than 100%, and is absurd.

Appreciation is an asset to be added to cost of reproduction new. The Committee is correct in the conclusion that appreciation is not to be used as an offset to depreciation. This conclusion is true because appreciation, being an item to be inventoried and valued as a part of the cost of reproduction new, cannot be used as an offset, any more than other items of the physical make-ups of the property can be used as such an offset. The solidification, seasoning, and adaptation of a railway is as real an item of construction cost as is the cost of haul of material from cut to fill.

"Development Expenses" (page 1329) should properly include the losses due to keeping the property up to the requirements of public use. Many items of permanent railway construction are abandoned because substitute structures must be built to meet the public needs. As an example, consider the abandonment, by the railways of the Southeast, of pile foundations for wooden trestles when public service forced the substitution of 10-ft. trestle spans for 12 and 13-ft. spans. There are single systems in the Southeast with more than 70 miles of wooden trestles. The foundation piles abandoned as a result of the public requirements will cost not less than $10 000 per mile. The abandoned property, being wood permanently moist, has a life expectancy that is practically perpetual.

Mr. Grunsky.

C. E. GRUNSKY,* M. AM. SOC. C. E. (by letter).—No one who has attempted a solution of the valuation problem as it is presented when the rates of public utilities are to be fixed, will underrate the amount of work done and the careful consideration which has been given by the Committee to the preparation of this report. It represents an earnest effort, in the light of the present state of the art, to lay the foundation for the procedure which should be followed when rates are to be fixed, on the assumption that the decisions of the Courts thus far rendered and as ordinarily interpreted are to be accepted as final. The Committee, however, has failed to recognize the fact that it is unwise to make "value", as called for by the Courts, which results from the earnings, the starting point when rates, and therefore earnings, are to be fixed. The Committee has accepted as reasonable the proposition that there need be no stability to the rate-base, that the rate-base may change with the changing value of the elements of which any public utility plant is composed, and that the determination of this fluctuating, constantly changing, "fair value" is necessary, because the Courts hold that "fair value" is the proper starting point.

The writer has written so much on this subject, and his views are so well known, that he will make his remarks very brief. He feels certain, however, that the method of procedure when rates are to be fixed under which the life of the utility, considered in its entirety, is regarded as unlimited, and under which the use of a definitely ascertainable rate-base (not controlled by value) is possible, has so much in its favor that it will, in time, be generally adopted. This method is not mentioned by name, but is closely related to the method described in the report as the "Replacement Method." The Unlimited-Life Method is, to be sure, a replacement method, but not such as would require the exact amount necessary in any year for replacements to be collected from the rate-payers in that year. Neither is its application limited, as suggested by the Committee, for the Replacement Method. The replacement requirement under the Unlimited-Life Method is to be forecast in a reasonable way, and suitable provision is to be made in the earnings to have the money for making replacements available when required. It is immaterial how the estimate is made; but it is essential that all funds collected for replacement purposes be properly accounted for. If the computation has been at fault, and the replacement fund is found after a time to be inadequate, earnings must be increased. If, on the other hand, there is inordinate accumulation in the replacement fund, then the allowance for the replacement requirement should be reduced. Under the Unlimited-Life Method of procedure the need of estimating the accrued depreciation of the entire plant falls away. The rate-base, once determined, remains unchanged until the plant is extended or modified, or until the public

* San Francisco, Cal.

desires to put itself into the position of part owner by retiring a part of the owner's invested capital. Mr. Grunsky.

The soundness of the theory on which the Unlimited-Life Method of procedure is based seems to have been generally recognized. The simplicity of its application and the advantage which it has of requiring lowest earnings in the early years of operation, will compel its general adoption or re-adoption whenever the Courts shall have found it desirable to modify their recent decisions which heretofore have been interpreted to hold that value must be made the starting point, ignoring, apparently, the fact, to which attention cannot be called too frequently, that value is not the premise for the determination of earnings, but is created by the earnings.

There is nothing which would prevent the Courts from receding from the position apparently taken in the Knoxville case, in which the United States Supreme Court said:

"If, however, a company fails to perform this plain duty and to exact sufficient returns to keep the investment unimpaired, whether this is the result of unwarranted dividends, over issues of securities, or of omission to exact proper prices for the output, the fault is its own."

This position, if it means rates at all times to yield earnings which will include so-called depreciation, is not sound doctrine, because the cases will be rare indeed in which, immediately on the beginning of operations, the earnings can be made adequate to keep the investment unimpaired. Some time must be allowed during which the earnings will fall short of the amount apparently called for by the decision of the Court. This time may be only 1 year, or it may be 5 or 10 years. If the opinion of the Court is regarded as applying with equal force to the years already past as to those yet to come, which seems to follow from the context in the decision, then either a sacrifice may be demanded of the owner, or the few rate-payers of the early years may be required to carry an unwarranted burden.

It is sound doctrine, and reasonable and fair to both the rate-payer and the owner, to estimate the required earnings so that there will be no immediate retirement of invested capital, but only suitable gradually increasing provision for necessary renewals. The renewal or replacement fund, however, can be regarded at any time as a return of capital, when the business is to be closed out, or when the public desires to participate in the ownership. A method of procedure is thus marked out, which is remarkably simple and makes unnecessary a consideration of value as the starting point when rates are to be fixed.

The rate-base thereunder will start with the capital reasonably and properly invested, not swelled by appreciation nor reduced by depreciation. This is substantially what Mr. James T. Shaw contends for

Mr. Grunsky.

in a statement presented on November 9th, 1915, to the Railroad Commission of California in the Telephone Rate Case (Application No. 1870), when he asks that the "actual performance" be made the "rate-base." In his argument, he reinforces the plea, which is being made by many engineers and economists, that value be regarded as a "result and not a premise."

Influenced perhaps by an earlier presentation of this subject by Mr. Shaw, the Public Service Commission of the State of Washington, in the proceedings relating to telephone and telegraph rates (Cases Nos. 1810 and 1825), on April 25th, 1916, says:

"The statute is silent upon the question of the finding of 'fair value' or a base for rates. The Commission is directed to find the 'market value', but no one contends that the 'market value' is always a fair basis for rates. Since the Commission is required to ascertain the fair, just, reasonable and sufficient rates for telephone service, the Commission will assume that it is authorized to find a 'rate base.'"

Relating to value as a basis for rate-making, the Commission says:

"If we take this definition of the term 'value' and make such value the basis for rate-making, each time we increase the return we increase the desirableness of the property or properties, and on the other hand if we decrease the return, we decrease that which makes the thing desirable; and so, if we decrease the return we decrease the value, and if we increase the return we increase the value."

* * * * * * *

"To say that rates are to be based upon the value of the property, using the term in its usual and ordinary sense, is to say that rates shall be based upon one premise to-day, another to-morrow. So we must conclude that when the Courts said that rates were to be based upon 'fair value', they could not have meant to use the word 'value' in the sense in which the word is ordinarily used and understood."

Some Courts, too, are beginning to recognize the futility of requiring that "fair value" shall be made the "basis of the calculation." Thus, for example, the Supreme Court of Idaho in a recent decision (1915), Pocatella Water Company case, Murray *vs.* Public Utilities Commission, reversing the Public Utilities Commission of that State, says in reference to depreciation:

"In other words, if it be demonstrated that the plant is in good operating condition and giving as good service as a new plant, then the question of depreciation may be entirely disregarded."

It is the duty of the valuation engineer and the economist to point out, as occasion arises, that it would be error on the part of the Courts to insist that "fair value" be made the basis of the calculation when rates are to be fixed. It may not be easy, however, to secure general admission that other procedures than the one thus far approved are sound. The Courts must act with caution, and must be convinced

beyond peradventure before taking a new stand. The writer believes, however, that the decisions which seem to determine what should be made the "rate-base" are not so final or explicit as to be removed from attack, or at least from possible new interpretation. The decisions of the Courts which make value the starting point, have been rendered to prevent confiscation of property and to protect rate-payers from inordinate exactions. The method supposed to be the only one acceptable to the Courts is illogical and difficult, and is practically impossible of satisfactory application, and yet there is available a simple, logical, and perfectly fair method of procedure, the advantages of which will be generally admitted whenever its application shall have obtained the sanction of the Courts. Mr. Grunsky.

Heretofore, the writer has called the attention of the Profession to the fact that the ordinary application of sinking-fund methods to compute the amounts which should go into a depreciation, or into a replacement, fund are materially in error.* It is self-evident that the actual term of usefulness of any article will never agree exactly with the term which was predicted for it when it went into use on the basis of probable life for articles of its class. When consideration is given to the departure of the actual term of service of individual articles from their probable life or expectancy, it will be found that the computation of the annual depreciation increment or of the annual replacement requirement is quite different from that computed in the ordinary way from their probable life.

It is not proposed to present conclusions on this subject, but only to express regret that the Committee did not take the time to ascertain, approximately at least, the magnitude of the effect of the departure of the actual useful life of articles from their expectancies.† The report is silent on this subject, and, being silent, only reflects the present unsatisfactory state of the art. Any one attempting to apply any method of procedure which involves a deduction of depreciation will find difficulty in making provision in the accounting for the individualized articles which go out of use before the end of their predicted term of usefulness, as well as for those which serve beyond this originally allotted term of usefulness. He will find that the Compound-Interest Method is not, as was originally claimed, an equal-annual-payment method, even when interest rates are uniform, that the Sinking-Fund Method might as well be discarded for an approximation method similar to the Straight-Line Method, and that the Straight-Line Method imposes an unwarranted burden on the rate-payers of the early years, which is undesirable and unnecessary. Any "present-value" method, as already stated, must be accompanied by

* *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 837; also, Vol. LXXIX, p. 761.

† See "Valuation, Depreciation, and the Rate-Base", by C. E. Grunsky, pp. 104 to 122.

Mr. Grunsky.

frequent re-determinations of value. Under all the methods described by the Committee, except the Replacement Method, bookkeeping will be a complicated art.

The application of the Compound-Interest Method of procedure is by no means as simple as the Committee assumes when, on page 1474, it says:

"There is no ambiguity in the foregoing described method; no chance for confusion; the method is exactly analogous to that described under the straight-line theory of depreciation."

This would only then be true if all individualized articles would actually go out of use at the ends of their respective probable life terms.

The Committee has not offered a satisfactory solution of a vexed question. It leaves the whole matter in confusion. Nevertheless, the facts presented in the report and the academic discussion of the results that would be obtained under various methods of procedure, on the assumption of certain premises, not to be realized in practice, is a valuable contribution to the literature on valuation and rate regulation, and will be of material aid in hastening the acceptance of fundamental principles and the general adoption of a satisfactory method of procedure.

The fact that the profit to which the owner of a public utility is entitled may be expressed in terms other than as an increment of the rate of return applied to a rate-base, has not been brought out in the Committee's report, and yet this deserves discussion, as it smooths the way for determining reasonable rates without starting with "value." The purpose of this extension of the writer's discussion* is to make this fact clear. The Courts are compelled to determine whether or not the allowed earnings are confiscatory. Consequently, they have concerned themselves with value, regardless of how it may have been built up. The rate-regulating authority, on the other hand, should be and is free to use any proceeding which to it appears to be convenient and equitable in determining what the earnings and, therefore, the rates should be. This fact does not seem to have been recognized or accepted by many of the public service commissions, and they, therefore, following the lead of the Courts, are nearly all concerned with the value of public utility properties and find themselves forced, in some cases, as the writer has instanced in his preceding discussion, to read new meanings into the word "value." If every property to be valued was new, there would be comparatively little difficulty in estimating the amount that should be assumed to be reasonably and properly invested therein, but there is serious difficulty when a property is no longer new. The service rendered by, or the output

* This is an addition to the previous part of Mr. Grunsky's discussion.

Mr. Grunsky.

of, a property which is mature and well-seasoned, is ordinarily better than, or at least as good as, the same service or output of a new plant. From the standpoint of the value of the service rendered, therefore, the rates determined for a new plant should be appropriate, too, for a plant the parts of which may show all manner of accrued depreciation. Except for the requirement apparently laid down by the Court that "value", interpreted to mean "present" or "depreciated" value, is to be taken into account, there is, in other words, no need at all of considering "accrued depreciation" (not to be confounded with "deferred maintenance") when rates are to be fixed. Consequently, as already stated, the principle of starting with a rate-base undiminished by depreciation is fundamentally sound.

When thus determined, however, something more than the rate-base is to be brought into consideration. The rate-base may express what the sacrifice was, which the owner had made and on which (to cover interest and expenses incident to securing money for the enterprise) he should receive an adequate interest return. In addition to an adequate interest return on such a rate-base, however, he may reasonably expect, and certainly is entitled to, compensation for management, and for business hazards; and he is entitled, also, to a participation in the prosperity of the community which he serves. In dealing with "value", it has become customary to include therein some allowance for "going value" and also to fix the rate of return on the resulting "fair value" higher than ordinary interest rates. A way has thus been found to permit the utility to earn more than interest on the investment. The business yields a profit. Unfortunately, it is difficult, if not impossible, to establish any fair or acceptable rule for determining the fair rate of return which ordinarily is to include the profit item. That this is difficult is due to the fact that one utility is of a character involving a large investment compared with the annual gross income, and another shows the reverse condition; a large amount of business is done on a small investment. Water-works may be suggested as of the first class, particularly when the areas owned for reservoir and water-shed purposes are extensive. Express companies suggest themselves as belonging in the second class. Their ownership of property and capital investment may be but nominal, although their annual receipts are large.

Why not give consideration, therefore, to the volume of business, to the annual gross income, as well as to a rate-base, when determining what the earnings should be? In other words, let the profit be brought into a fair relation to the volume of business, instead of attempting to predicate it on the rate-base, or that uncertain element, "value", which is, in part, created by the profit.

When an interest return is allowed to the utility, which will cover the cost of money borrowed for legitimate enterprises of the character

Mr. Grunsky.

of such utility, and this interest rate is applied to a rate-base estimated from legitimate proper investment undiminished by accrued depreciation, certain profit allowances, about as noted subsequently, will be found to be appropriate. It is assumed that, in determining the cost of borrowed money, due allowance will be made for discounts and commissions. The profit allowances, if made as suggested, would represent compensation in lieu of current appreciation and interest on the going value, or other elements of value not included in the rate-base. In the last analysis, however, the capitalization of this profit allowance would show that intangible values have actually been created and are demonstrable. The reversal of the usual procedure appears to be advisable. Instead of starting with the intangible values which are to be created by the earnings, let the profit be fixed, and the intangible values will take care of themselves. The suggested profit allowances are as follows:

When	gross	income	is	$10 000	about	15%	$1 500	per	year.
"	"	"	"	100 000	"	14.5%	14 500	"	"
"	"	"	"	500 000	"	13.5%	67 500	"	"
"	"	"	"	1 000 000	"	12.5%	125 000	"	"
"	"	"	"	3 000 000	"	10%	300 000	"	"
"	"	"	"	5 000 000	"	9%	450 000	"	"
"	"	"	"	10 000 000	"	8%	800 000	"	"
"	"	"	"	20 000 000	"	7%	1 400 000	"	"

"	"	"	"	100 000 000	"	5%	5 000 000	"	"

The allowances here suggested as additions to the interest return on the rate-base are only tentative, and remain subject to modification on further study. Furthermore, no such general suggestion as is here made could be expected to fit every case. These allowances, moreover, are intended to apply under ordinary conditions, and do not cover the larger return which the owner has a right to expect under the unusual condition when, by introducing a new invention or a less expensive process, which may be the direct result of his efficient management, he has reduced materially the cost of his output.

In such an event, the resulting benefit should go to both the owner and to the rate-payer, and the owner should be recompensed for discarded property, rendered useless perhaps by the new invention, but, necessarily, put at once into the class of property no longer in use. It would be proper in such cases, without imposing hardship on the rate-payer, to allow the rates to remain as they would have been without taking account of the reduced cost of production, at least long enough to amortize completely so much of the original plant as the new invention has rendered useless. After this amortization is accomplished, the rates will be subject to such adjust-

ment as will bring the rate-payer into fair participation of the benefit which has resulted. If any policy less favorable to the owner was followed, he would find it to his advantage not to make any innovations which would require the abandonment of a part of his plant still in serviceable condition. He could not afford to assume new hazards resulting from the investment of more capital, unless he felt sure that his profits would be increased thereby. Mr. Grunsky.

JOSEPH MAYER,* M. AM. SOC. C. E. (by letter).—For a thorough investigation of valuation and the therefrom inseparable regulation of public utilities, the nature of the economic problem which must be solved and the kind of solution desired must first be defined clearly. Mr. Mayer.

In competitive private industry the owner, generally, is practically at liberty to choose the prices for which he is willing to sell his products, provided free competition is not in any way interfered with.

The public relies on competition to increase automatically the supply and thereby reduce the prices whenever they are such as to produce for a long time much larger average profits in any industry than are secured in other industries offering otherwise equal advantages.

Experience shows that, in many industries producing the necessaries of life, competition is extremely limited or impracticable, and that excessive prices, producing unusually large average profits on investment, thereby arise. Such industries are pre-eminently street railways, the distribution of gas, electricity, and water, telephone and telegraph service, the carrying off of sewage, local, and to a less extent long-distance, railways, and express service.

Capital is obtainable for these industries if the prices of their products or services are regulated so that average profits are the same as in competitive industries. The practical problem is to find such a regulation of monopoly prices as will equalize average monopoly and competitive profits without interfering with efficiency of management.

One method of price regulation is to introduce public ownership and operation, as is done universally with sewers, largely with water supply, and, to some extent, with others of the industries mentioned.

Public operation of monopolies, due to gross inefficiency of management, has often proved a failure. Private operation, with public control to secure fair prices without destroying efficiency, therefore, is attempted.

To secure efficiency with private operation, the net revenue of each enterprise must depend on its efficiency of management. This cannot be attained by regulating the prices so that the individual enterprises secure a uniform rate of return on the investment. For fairness, the prices must be regulated so that the average rate of net return on the investment in every regulated industry, not that in

* Hollywood, Los Angeles, Cal.

Mr. Mayer.

individual enterprises, is the same as this average net return in such competitive industries at the same time and place as offer otherwise the same advantages.

The Committee advocates a standard rate of return on the investment in every individual normal enterprise, practically ignoring differences of efficiency. It defines a normal property or enterprise as one which is neither overbuilt, inadequate, nor improperly located. The Committee, though advocating and assuming in its ascertainment of the tangible value a regulation ignoring the existence of differences of efficiency and the consequent fairness of unequal rates of return, endeavors, in a hesitating manner, to correct the therefrom resulting errors in the chapter on "Intangible Values."

The aims pursued by the Committee and the writer become thereby much less divergent. The writer, however, claims that these aims cannot be attained by the circuitous method adopted by the Committee. The Committee tries to follow closely the decisions of the Courts in determining values. The writer believes that, as value is an economic phenomenon, it must be determined by studying economic laws, and not legal decisions merely. Economists, not Courts, are competent valuators. The Courts acknowledge this by only stating correctly what factors influence value and must, therefore, be considered, but refraining from prescribing how value is to be determined from these factors.

The Courts insist on fairness, and keeping promises is the most important guidance in determining what is fair. The writer, therefore, believes that the first task in valuation is to ascertain what promises have been given. This is a political and partly a legal question, wherein the laws and the decisions of the Courts are final. The second task is to find what values result from keeping promises, and this is a purely economic question. Court decisions which contradict economic laws cannot stand, and will be reversed as soon as this is clearly demonstrated.

The decisions quoted in part by the Committee on page 1372 indicate that the Courts sustain the determination of value in the ordinary economic manner, that is, from estimated future net revenue and market quotations, and do not sustain the theory that a public service property is entitled to a standard return on either actual cost or cost of reproduction less depreciation, which underlies the assumption that costs are values.

In competitive industry it is held to be fair that the investor obtains a greatly varying rate of return on his investment, the amount of which depends mainly on the industrial capacity of the promoters and managers of the enterprise, but partly on changes in the industrial world occurring independently of the management. Competition

is relied on to assure the fairness of prices. The independence of private ownership is only practicable when the owner secures the profit and loss resulting from judicious or injudicious choice of enterprise, from good or bad design, or from other differences in efficiency of management. The Committee proposes in its main argument that the fairness of regulation be judged by the return secured by individual investors. The writer maintains that, with private property, this is not practicable. The return of the individual enterprise must vary greatly with efficiency, and the efficiency can only be practically judged from the rate of return secured under conditions prescribed in some other way than by trying to secure a uniform rate of return in individual enterprises. Mr. Mayer.

The Committee not only advocates such a regulation, for natural practically complete monopolies, as will give a uniform rate of return in individual enterprises, but assumes in much of its reasoning that such, if any, regulation has actually existed in the past and ought to have existed where all regulation was absent. As a matter of fact, no such regulation ever did exist, and never ought to exist. Many of the Committee's inferences in regard to values, depreciation, and the proper future rates based on such assumptions, therefore, are in error. The activity of regulating commissions is generally limited to reducing grossly excessive prices where consumers complain. They then endeavor to fix such prices as will, in their opinion, with average efficiency of management, produce about the same rate of profit as in local competitive industries at the same time. The price adopted is mostly and necessarily, since the required facts are missing, an approximate guess, unsupported by adequate evidence. Actual values of enterprises thus regulated, therefore, are widely different from those which would have resulted from the imaginary regulation advocated by the Committee, and which it endeavors to determine.

Where competition remains an important element, no attempt is ever made to secure a uniform return on the investment in individual enterprises, for the very good reason that it would not be practicable. The fundamental principle which governs commerce and should govern regulation and valuation is: "Be careful what you promise and keep your promises."

In granting franchises, in the past, the public, generally, has not been careful in its promises, and has often made it very difficult or impossible, without gross injustice, to keep the promises it made. The economic developments of the present were not foreseen in the past, and the promises made were so extremely indefinite that it is generally impossible to determine accurately what was promised and to keep accurately the promises. In commerce, it is sometimes found

Mr. Mayer.

just, under exceptional unforeseen circumstances, by a moratorium to relieve merchants of given promises to pay their debts when due.

The case of unreasonable public franchises is in some respects similar, and there are cases when justice requires expropriation on fair terms. Regulation was introduced that was not provided for in many of the franchises, and was frequently modified in such an unexpected manner as to affect seriously the net earnings and thereby the values of enterprises. Though the principle of keeping promises is thus frequently disregarded, it nevertheless remains a valid principle whenever it is possible to follow it without serious injustice. Another necessary principle governing valuations follows from the nature of value.

From the definition of value, cited by the Committee in the Glossary, it follows that the value of a public utility, the securities of which are largely dealt in on the exchanges, can be most closely obtained from a study of the quotations in the stock exchanges, and the amount of securities outstanding. The security quotations represent an estimate by the market of the present value of the future income expected to be paid to the owner of the securities.

This future income and the current quotations measure the value of securities, and they are what the owner values and what the Courts endeavor to protect. The future income depends largely on the future regulation. This latter is not exactly known, but its nature is inferred from the present legally established regulation and the knowledge that the Courts, generally, will not sustain such changes of the existing regulation as will destroy present values, as well as from the necessity of regulating prices so that it will be possible to secure the needed capital for building new properties, for extending old ones, and for rendering satisfactory service.

To ascertain the present values of future revenue, the rates of interest to be adopted must be known. Such rates must be chosen as will make, for enterprises the securities of which are largely dealt in on the exchanges, the value inferred from future net revenue the same as that inferred from the security quotations. The Committee proposes to find the values of public utilities by determining first the tangible and then also the intangible value, giving the latter due weight.

By strict logic, the total value is equal to the tangible plus the intangible value, and as the intangible value is equal to the exchange or market value, derived from estimated future net revenue and quotations, less the tangible value, their sum, or the total value, is equal to the exchange value.

The determination of the tangible value, therefore, is at best only indirectly useful for the purpose of valuations. The Committee pre-

fers, however, not to be logical. It infers, from the fact that the Courts give round sums for the intangible value, that the entirely indefinite phrase giving due weight to the intangible value must be substituted for the exact request to add the intangible to the tangible value. There is abundant reason for using round figures for the result of any valuation, however determined. It is improper to use exact figures when the degree of accuracy obtainable by any kind of valuation does not justify anything else but round ones. Another reason given is that the Courts do not assert that the value must be found by considering income and quotations alone. It might also be stated that the Courts expressly assert that costs are one element to be considered. The Courts, however, do not state how the value is to be determined from the various elements which must be considered. The cost and the average life of every perishable part of an industrial enterprise must be known in order to determine its annual decretion which is a part of the operating expense. The net earnings, therefore, cannot be determined without knowing the costs of the perishable parts of the plant. For determining what prices must be allowed to secure capital for enterprises capable of rendering the same service, and thereby to choose a fair regulation, the costs of a substitute enterprise are of importance. In a valuation based on net revenue, costs, therefore, are considered in two ways: First, in choosing the regulation to be assumed; and second, in determining the net earnings resulting therefrom. Mr. Mayer.

The Committee endeavors to show that the kind of regulation it advocates does not necessarily destroy efficiency. For this purpose it again departs from logic. It desires a regulation which makes tangible value equal to exchange value. This can only be attained by making the return on the investment proportional to its amount. It then recommends a departure from this uniformity by advocating the London and Massachusetts sliding scale of dividends.

The instance cited is the allowed 7% dividend for 90-cent gas with ¼% increase of dividend for every cent of reduction in the price of gas. The gas company, under this rule, now obtains 9% dividends with 80-cent gas. In competitive industry, when a producer reduces costs of production he obtains himself the profit from the reduction of cost until the improvement is adopted by enough of the competitors to increase the supply materially; then prices and the profits of all producers are reduced, and the backward ones are compelled to improve, or receive abnormally low profits. After a short time, average profits are the same as before, and the public gets the benefit of the improvement. During the transition period, those in advance gained, those in the rear lost.

Mr. Mayer.

With the sliding scale, when an improvement reducing costs is made by any one and widely adopted, all, whether fast or slow, obtain a permanent increase of dividends.

The inducement to make the first trial of improvements is greatly reduced; that to wait until they are well tried out is increased.

Improvements are discouraged, and permanent excessive dividends result from those adopted. The sliding scale is unfair to the public; therefore, it does not spread. The two requirements, fair prices and high efficiency, are not, and cannot be, secured by the methods of regulation advocated by the Committee. They can be secured by improved franchises for all natural monopolies.

The franchises should all be definite competitive operating contracts for limited periods of time.

Such a contract should be based on unit prices for the work performed, which work should be as accurately described and enforced as that described in a contract for building a large engineering structure. The contract must contain such clauses, referring to decretion and the compensation for the plant of the contractor, if any, at the end of the operating period, as will assure adequate maintenance and exact determination of the payments for such plant. If old, the property forming the subject of the operating contract must first be obtained by the public by a valuation based on the present value of the future net revenue with the present regulation, unless good reasons exist for believing that the present regulation is unfair. In this latter case, such a regulation, in harmony with promises made, should be assumed as will make it possible to secure capital for new properties capable of rendering equal service and for extending and satisfactorily operating old ones. If there is a good market for the securities, the value should also be determined from a study of the quotations.

For valuing the property and, later, for determining the annual decretion, an inventory must be made giving an estimate of the original cost, age, and average life and scrap value of every perishable part of the plant; or, where these are unobtainable, an estimate of the present value, the remaining life, and the scrap value.

For determining every year the decretion of the plant, which is a part of the operating expenses, the decretion must be defined so that it can be accurately determined and so that it agrees as closely as possible with the facts.

The following rules will serve for this purpose:

The nominal annual decretion of any part is the difference between its cost and its estimated scrap value divided by its estimated average life. The actual life and scrap value are different from the estimated average life and the estimated scrap value. To correct the errors

resulting therefrom, the following rules become necessary for calculating the actual decretion every year. Mr. Mayer.

For parts in use and younger than their estimated average life, take the nominal annual decretion; for parts in use and older than their estimated average life, take no decretion; for parts discarded during the year, take the cost less the decretion previously allowed for, and consider the actual scrap value as part of the earnings.

These rules take an estimated decretion for parts in use for which the actual one is unknown, and correct the therefrom resulting error as soon as the actual decretion becomes known by the discard and sale of parts. They, therefore, give as close an approximation as practicable of the actual decretion.

By means of the inventory and the rules for decretion received by the bidders, the decreted cost of the plant can be ascertained at the end of every year. If the decretion thus determined is considered a part of the operating expense and placed in a decretion fund to be used for replacements, improvements, and extensions, without thereby increasing the cost accounts, the plant will be efficiently maintained.

New capital is required for most plants, and any operating contract must contain clauses prescribing who is to furnish such capital for extensions and increase of capacity, and the compensation it is to receive. The public is interested in all parts of the plant which may survive the contract, and a board of engineers representing the public must have a controlling voice in selecting and supervising the acquisition of new plant. An operating contract must describe the kind of service wanted as well as the maximum prices to be charged, based, in an old plant, on the previous ones, with such changes as appear advisable at the time of framing the contract. The operating company should be permitted to reduce, but not to increase, the prices. The contract should be framed by representatives of the public. Invitations to bid should be sent out giving all the available information required by bidders to assist them in calculating the net earnings during the period of operation, which might be about 20 to 30 years. The company should be required to surrender the plant at the expiration of the contract at cost of the parts, if any, furnished by the contractor, with the approval of the representatives of the public, during the period of the operating contract, the decretion fund going with the plant.

The bidders should be asked to give the annual rental which they are willing to pay. The contractor must furnish a guaranty for at least one year's rent, which should be payable monthly out of the net earnings, if possible. If the guaranty fund is encroached on, the contractor should be required to replenish it. A quick foreclosure, in case of non-fulfillment of conditions, should be part of the contract.

Mr. Mayer.

By such provisions, large contracts can be awarded safely to bidders backed by a moderate capital. This will make real competition possible for every large enterprise.

This, though quite incomplete, will give a general idea of the kind of definite competitive contract that should replace the present indefinite franchises, in which protection of the interests of the public is obtained by commissions having, among many other indefinite powers, that of prescribing and changing without compensation, after award of the franchise, the prices of the products and services furnished by the operating or owning company. Changes are necessary in any long-term contract. Therefore, there must be provision for making them without changing the value of the contract.

The two contracting parties should be on an equal footing, and their respective rights and duties should be defined exactly.

With such a contract, fair prices would be assured by competitive bids for contracts of such size as will assure active competition.

Efficiency is secured because the profit or loss of the contractor depends entirely on his efficiency. The drawing up and enforcing of such a contract does not require the superhuman knowledge and ability that would be necessary for assuring efficiency and fair prices by the present methods of regulation. Only one valuation is required for each old enterprise, that for acquiring ownership of the property. All succeeding transfers would take place for sums based on costs and decretions, defined in advance so that they can be determined accurately.

Reviewing the foregoing discussion: the problem to be solved is to replace adequately the self-regulating competition which has disappeared either partly or altogether in some fields of productive industry. Where free competition prevails, fair prices and efficiency are secured automatically by increased supply and falling prices, in industries where average profits are excessive, and reduced supply and rising prices where they are abnormally low. The fairness attained is not equal profits for good and bad management but, in the long run, approximately uniform average profits for the same degree of industrial capacity in different industries. Efficiency is secured by profits depending mainly on it. The return on the investment in the individual enterprises of every industry varies widely with the economic skill shown in their promotion and management, and partly with unforseeable economic changes outside and independent of the management. The board of directors, consisting of, or representing, the largest stockholders, has generally no other common primary aim than the, in the long run, largest possible return on the investment. The value of the business may be a small fraction of the investment or may exceed more than ten times its amount. An industrial enter-

Mr. Mayer.

prise is a tool for the production of a future net revenue; its value is the present value of its future net revenue; this, on an average, depends mainly on the cost of production of the business, but, in individual cases, mainly on the industrial capacity of the management. This deviation of the value of such an enterprise from its cost of production is what produces efficiency of promotion and management without public control, and makes private property of such enterprises practicable.

The directors will endeavor to secure, and will retain, the most efficient managers. Were uniform profits guaranteed, as is proposed for the ideal regulation of the Committee of completely monopolized industries, a crowd of incompetent promoters would encumber the field of new enterprises, and the directors would probably choose their sons, nephews, and friends for the leading positions, and would follow the same method in selecting the minor officers.

Since, with uniform profits, the public pays for good or bad management and carries the risks, it will gradually insist on full control of promotion and management, independent private property will disappear, and public operation and ownership will result almost automatically. Uniform profits for individual enterprises are incompatible with private operation, because, inevitably, they destroy efficiency of management. The only possible alternatives, therefore, are public operation, and private operation with profits in individual enterprises mainly depending on efficiency and with average profits in every monopolized industry, the same as the average profits of competitive industries at the same time and place.

The frequent inefficiency of public operation in democratic communities arises from the method of choosing the public equivalent of the board of directors, and the general manager and his assistants. They are either elected directly or are appointed by representatives elected for other qualities than their knowledge of the industrial enterprises under public management. The voters and their representatives generally know little about these industries.

The management is controlled frequently by the most powerful politicians of the day, and will remain in power through its control of votes. It is often dependent on the politicians in its appointments and discharges of employees and the choice of their salaries and wages, in the prices charged for services rendered to the public, and sometimes, also, in its purchases of materials and supplies as well as in the choice of improvements and extensions.

In attaining and keeping in power, the efficiency of management is a very small factor, and, therefore, is largely neglected.

A private board of directors in a company with a fixed rate of dividends would be worse, but a private board with a rate of dividends depending mostly on efficiency is far superior.

Mr. Mayer.

There is, therefore, no reasonable doubt that, as long as the evils described prevail, private operation will secure a cheaper and better public service when the net earnings of the private company depend mainly on efficiency of promotion and management. One way of securing the fairness defined as equal average profits in each monopolized and in competitive industries, combined with the efficiency of management resulting from profits in individual enterprises depending mainly on efficiency, consists in replacing the kind of competition which has disappeared, because it is impracticable, by another kind which is practicable. This consists in acquiring public ownership of all partial and complete monopolies, and selling definite operating contracts for limited periods to the highest bidder. Two necessary features of such contracts, which have been given insufficient attention in past franchises, are an exact definition of the annual decretion and of the price to be paid to the contractor or owner, either when he fails to comply with the terms of the contract or at the end of the operating period.

Another feature of such contracts, not mentioned in the foregoing, is the possibility of prescribing exactly in the contract, without injustice to the contractor, the minimum wages and other working conditions approved by public opinion, and the manner in which they are to be changed without changing the value of the contract.

Near-by economic changes, occurring independently of the contractor and influencing the net earnings, can be foreseen largely by the bidders and allowed for in the bids. Distant changes, which cannot be foreseen, will influence future bids in the same manner. Approximate proportion of efficiency and net earnings will be secured thereby. In such contracts changes in the value of the lands occupied by the enterprises accrue mostly to the public to whom they belong. They are caused largely by events beyond the control of the contractor. Justice requires, therefore, that they should not affect his revenue. In these respects public ownership with the private operation herein described is more just than private property in competitive enterprises. Another advantage is the much greater stability in the value of all securities representing part of the income of either the property operated or of the operating contract. With publicity of accounts and exact determination of the annual net earnings, the value of the contract can be judged much more accurately than that of a partial or complete monopoly regulated in the present necessarily arbitrary manner.

Transfer of the property from one operating company to the next, based on costs, when agreed on by contract, is far superior and is more just than transfer based on values. Costs can be ascertained accurately when followed from the start, values never; costs make the contracts

definite, values indefinite. This change from the general practice of using values instead of exactly defined costs, in defining the terms of transfer, is what makes short-term operating contracts practicable. The other method of securing fair prices, together with efficiency (which are both essential), is to fix, by regulating commissions, from time to time, the kind and quantity of service to be furnished by partial or complete monopolies and the prices which they are permitted to charge. Mr. Mayer.

The prices are fair when they make the average profits in every monopolized industry the same as in competitive ones; they secure efficiency when the profits in every individual enterprise are in proportion to efficiency of management. To fix the prices, it is necessary, therefore, to ascertain, first, the average profit secured in competitive industries at different times and places. By profit of an enterprise is meant the percentage of net earnings on its value. The sum of the values of a large number of well-selected competitive enterprises and the sum of their net earnings must be ascertained. The latter multiplied by 100 and divided by the former gives the average competitive profit.

Though the value of individual competitive enterprises varies greatly from their cost of production, the sum of the values of a very large number, representative of all competitive enterprises, is approximately equal to the sum of their costs of production. This results from the tendency of capital to flow to the most profitable investments, which makes the average return of all kinds of otherwise equally attractive competitive investments the same. The value of the sum, but not the value of each, can be determined, therefore, from cost of production. The average profit of competitive enterprises can be determined, therefore, if the necessary facts are ascertained.

With any given regulation, the average profit in any monopolized industry can be determined in a similar manner from the sum of the net earnings and that of the costs of production of the enterprises. The average profits thus ascertained should be the same in competitive and in every monopolized industry. This assures fairness of the regulation as a whole. If the profits are found to be different, the regulation should be changed so as to make them alike.

The regulation in detail must prescribe different prices in different places with different costs of production. The differences in cost of production in different places with ordinary methods of production, therefore, must be ascertained.

Although it is theoretically possible to regulate fairly in this manner the prices of monopolized industries without destroying efficiency, the practical difficulties are too great for the exact application of this theory. The profit of competitive industries varies from time

Mr. Mayer.

to time and from place to place, and that of the various monopolies should vary in the same way. The necessary facts are unknown and cannot be determined accurately, and the necessary calculations would be extremely complicated. An enormous staff of regulators would be required to apply the theory.

The various regulating commissions cannot use this method, because they have neither the needed facts nor the staffs to gather them. Therefore, to simplify the method, a tendency toward uniform profits, where the management is not grossly inefficient, is inevitable. Regulation is generally only undertaken where there is complaint of excessive prices, so that the actual regulation is generally extremely sporadic and intermittent, and it does not follow consistently any theory, because this is practically impossible. The decisions of the regulating commissions, therefore, cannot be foreseen, and often appear to be quite arbitrary.

A very serious consequence of the, at present, extremely indefinite relations between the natural monopolies and the public is the uncertainty regarding the prices which will be permitted by the regulating commissions and the consequent large fluctuations in the market values of their securities. These commissions are directly or indirectly selected by, and are responsible to, the public, one of the parties to the implied contract between it and the utility companies. The principal protection of these companies is the impossibility of securing capital for new properties, extensions of old ones, and adequate service, unless sufficient return is allowed on the existing investment. The uncertainty of the return and the fear that it may not be adequate prevent new investment, unless a large return is allowed to compensate for the apparent risk. The regulating commissions may fix such prices and consequent returns as will attract capital and make it thereby possible to supply adequate public service. Such rates of return may be thought to be excessive by the public, unless the inadequate service with lower ones is felt to be the greater evil. Inadequate service, therefore, may lead to higher rates of return than adequate service, a condition which is evidently not conducive to the best service. Long-continued, inadequate service by private companies will create a demand for a radical change. Unless a way out, which will be an improvement over present conditions, is made widely known and adopted, a successful agitation for public ownership and operation seems to be inevitable. With definite competitive contracts any practicable and desirable kind of service can be obtained by the public by paying the necessary competitive price. As most of the risks incident to arbitrary regulation disappear with definite contracts, investments in them are comparatively safe, and will attract capital at low rates of profit. Most of the capital required would be secured by Government bonds at very low rates of interest.

Mr. Mayer.

The law ordering the valuation of interstate railways by a Federal commission was the result of a widespread belief that the capitalization of these roads was largely fictitious and far beyond their cost of production. It ordered, therefore, the determination of the actual costs of production to date and of reproduction less depreciation, so that they might be compared with the known capitalization, in order to ascertain the difference between them.

The Committee has done an enormous amount of valuable work to ascertain the principles for determining these costs and the depreciation. It has not determined values, however, or the correct principles of valuation. What it calls tangible value is not a value, but a cost of reproduction less depreciation. In the writer's opinion, the Committee has not altogether abandoned widespread erroneous views in regard to the nature of value, though it gives, under value and market value, correct definitions of value, of price, and of market price.

The identification of value and price is harmless, as long as the value of money remains substantially constant. The corrections necessary with changes in the values of money are a separate problem, not discussed by the Committee.

The determination of costs meets the demands of the Federal law prescribing it. The unsatisfactory chapter on "Intangible Values" attempts to meet the demands of the Courts which insist on the consideration of revenue and market values. With a slight correction, prescribing the addition of what the Committee calls tangible value, and of intangible value to obtain the total value, its valuation is correct. The demands made by the nature of economic phenomena, which prescribe the highest laws to which all others must accommodate themselves, however, are but imperfectly met by the investigation of the Committee. The value of an industrial enterprise of any kind is the present value of its future earnings. Security quotations, where available, give the fluctuating opinion of the market on the value of the securities. There are often no reliable quotations; the estimated future earnings with a fair regulation furnish then the means of determining values.

For determining what is a fair regulation, costs and depreciations must be ascertained. The Committee has given the principles which must be followed in determining these, and has thereby done part of the work necessary for a correct valuation, but it has not given the principles which must be followed in a real valuation based on revenue and quotations. The task which is now being performed by the Federal Commission for Valuation is, in reality, a cost determination and not a valuation, which latter will not be attempted. The Commission thereby conforms with the spirit and real purpose of the Federal law. Its work will be very useful in improving present methods of regulation of public utilities, but will be inadequate for valuing them.

Mr. McCann.

W. R. McCann,* Assoc. M. Am. Soc. C. E. (by letter).—It is readily to be conceded that the Committee has produced a very creditable and momentous work. The task of developing any sort of unanimity from the chaos which has heretofore existed in matters pertaining to the valuations of railway and other public utility properties is an estimable performance that is appreciated best by those who are daily engaged in valuation work. The Engineering Profession as a whole, and particularly those members thereof who have to do with appraisals of public utilities, owe a sincere debt of gratitude to the authors who, by exhaustive research and by many conferences, have succeeded in producing a report which purports to represent and reflect the Committee's unanimous, composite idea of valuation theories. Such a report will carry great weight indeed, in the future, whenever it is quoted and referred to as an authority; and its two hundred pages will be fingered many times by youthful engineers, apprenticing in appraisal and valuation work. The extended scope of the report, and the important utilization of its contents, should render engineers quite cautious in concurring indiscriminately with all the statements and theories therein, even though advanced unanimously by the Committee.

It is not to be expected that the Committee could produce a report which would be generally approved by the Society's membership. It is much more probable, judging from controversies which have arisen over the subject matter in the report, that every statement therein has its opponent. The question is, "Does the Committee's report on valuation of public utilities reasonably represent the status of the art to-day?" The writer believes that the question must be answered in the negative, particularly from the point of view of the regulatory bodies and the judiciary, which are charged by statute with establishing equities between utility companies and their consumers.

In a great many respects, the report is quite favorable to the positions heretofore taken by corporations. A careful study of it makes manifest the conclusion that hardly a scrap of a claim which will result in enhancing the value of utility property is neglected, unless it is obvious, after many a try-out before commissions and Courts, that the claim manifestly is to be disallowed. There is great danger in following the report implicitly; young appraisers and students, particularly, may be led astray, with the result that they may recommend (often advocate) absurd conclusions derived from adhering too strictly, without the exercise of mature judgment, to the Committee's leanings.

To point out all the places wherein there is much more to be said in behalf of the public's side than has been stated by the Committee would consume as much space as the report itself, and even more.

* Washington, D. C.

Mr. McCann.

Such extensive purpose is not the writer's intent in this limited discussion; he will confine his remarks to one important subject, that of "Original Cost to Date"—a matter which has been given but five pages, as contrasted with about a hundred pages (nearly one-half of the entire report) given to the antithetical theory, the "Cost of Reproduction."

It is to be frankly conceded that much of the language of the Courts to date has been favorable to the reproduction theory of valuing utility property; and it is also opportune to remark that a considerable portion of the judicial language has been misquoted, misrepresented, and misconstrued by partisan advocates. It is not to be overlooked, moreover, that the strength of original cost is to be found in commission decisions; and this is especially significant in that those who devote their entire time to the solution of valuation, rate-making, capitalization, and other problems affecting public utilities have marked leanings toward the equities inherent in the original-cost method of valuation. In the writer's opinion, the day is not far distant when the Courts, on review of a record which contains a commission decision embracing a valuation based on a properly compiled original-cost appraisal, will comment much more favorably on the original-cost method than they have on divers reproduction theories.

Heretofore considerable discredit has been given the original-cost method, due to confusion which has existed as to what is meant thereby. The capital account carried on a utility's books has been taken to mean the original cost of the property; likewise, it is argued that the purchase-and-sale price in a trade consummated years after the original construction represents the original cost of the property; also, the original sum invested in the nucleus of a property has been assumed to be representative of the original cost. These are not correct definitions. A proper original-cost appraisal is as capable of precise definition as is any reproduction theory. Before proceeding further with this discussion, it is well to bring out what constitutes a sound original-cost appraisal.

The California Railroad Commission,* submits the following definition of the term "original cost":

"The term 'original cost' means the actual expenditures chargeable to capital account, in accordance with the Interstate Commerce Commission's or this Commission's classifications, in cash or its equivalent in terms of cash, by the public utility for its property in the State of California, as of the date of the valuation."

Mr. Hammond V. Hayes,† a consulting engineer of Boston, defines actual original cost, thus:

"The actual original cost is the sum of money which was expended by the undertaking for the property now in use for the benefit of the

* Annual Report for the fiscal period from July 1st, 1915, to June 30th, 1916, p. 92.

† "Public Utilities: Their Present Fair Value and Return," pp. 123-124.

Mr. McCann.

public. It is not what the original property cost but rather what the present property cost. The expression 'original cost' is liable to convey a false impression. What is required in a valuation is the 'actual cost' of the property now in use. The term 'original cost' has been used so generally in decisions of courts and commissions, however, that it cannot be now eliminated. * * *

"The actual original cost should not be considered to be the cost of the first unit of plant used in a particular place or for a particular purpose. Items of perishable property, which are no longer in use or useful, cannot be considered as a portion of the property to be included in a valuation for the purpose of determining the fair value for rates. Such items of property have passed out of existence and their cost should have been removed from the books of the company as a portion of the value of its assets. If the business of the undertaking had been conducted properly, reserves for renewals would have been made. These reserves are obtained from users as a portion of the charges paid for the service. Manifestly it is unfair to the users for the company to demand from them rates sufficiently high to create a fund for the replacement of obsolete items and then include the cost of such obsolete items in a new value upon which new rates should be based."

Mr. Robert H. Whitten,* of Brooklyn, likewise defines actual original cost:

"Strictly speaking, actual cost means cost of original construction plus cost of additions and betterments. It excludes all expenditures for renewals and replacements including supersession due to obsolescence or inadequacy. It includes only construction, additions and betterments that are a proper capital charge under approved accounting principles. This conception of actual cost, however, is one that has in the past been very imperfectly comprehended. Correct accounting principles are of comparatively recent acceptance and application. The references made by courts to actual cost or original cost plus improvements show that in most cases they have loosely interpreted the term to include many things that are not properly a part of the actual cost of the present property. In certain decisions it is apparently assumed that actual cost or original cost includes discount on securities issued, exorbitant profits to promoters, cost of replacing worn-out or superseded property, dividends paid out of capital, money sunk in unsuccessful experiments. That is, the term is considered as an equivalent to book value inflated by financial manipulation or loose accounting. Considered in this light, it is little wonder that 'original cost' has been discredited as a standard of valuation.

"Actual cost properly considered is the most natural and in many respects the fairest single basis for the determination of fair value for rate purposes. A fundamental principle of public service regulation is that as the public service corporation devotes its property to a public use it may consequently be required to render the service at reasonable rates of charge. Rates of charge to be reasonable may not be in excess of the fair value of the service and may not be higher than necessary to produce a fair return on the property devoted to

* "Valuation of Public Service Corporations," pp. 82–83.

a public use. The measure of the property devoted to a public use is undoubtedly, in the first instance, at least, the money that the company has actually and necessarily invested, *i. e.*, the actual cost." Mr. McCann

Mr. Halford Erickson, ex-Chairman of the Wisconsin Railroad Commission, in a paper entitled "Depreciation and Its Relation to Fair Value", read before The Utilities Bureau in November, 1915, comments similarly on the definition and application of an original-cost appraisal, as follows:*

"By original cost in this connection it seems to me should be understood the cost at which the existing property used by public utilities in rendering service was acquired. By cost of reproduction is meant the cost of reproducing the existing property under prevailing conditions. The original cost of the existing property should be shown by the books and records of the utilities provided these have been properly kept and are still in existence. When the books have not been so kept or are not available, the original cost as thus outlined may be determined very much in the same manner as that in which the cost of reproduction is found. * * *

"When the original cost of the existing property is desired it can be computed upon the same inventory as that used in determining the cost of reproduction and upon prices which cover the period when the property involved was put into the plant. Such price lists may be had partly from the records of the plant and partly from other sources. In this way the original cost of the existing property can be had with even greater accuracy than the cost of reproduction."

The following statement of the Committee (page 1355) follows the identical line of reasoning, to wit:

"As original cost to date, with comparatively few exceptions, is not the book cost of the property but the cost of the existing items, it will be necessary as a rule to make a schedule of the various existing property items, in the same way that one would be made for determining the cost of reproduction; then reference would have to be made to the accounts, to ascertain the unit costs of the items."

The term "Original Cost" is used by the Engineering Department of the State Public Utilities Commission of Illinois to mean the actual expenditures, in cash (or its equivalent in terms of cash), made by a public utility for used and useful property which is properly chargeable to capital account and is embraced in an actual inventory; or, in the absence of records and books of accounts showing the actual expenditures, the estimated cost of the property as of the sundry dates of the installations of the various items of property is to be considered the original cost thereof.

Bearing in mind the aforesaid definitions of what constitutes a reasonable original-cost appraisal, particularly the definition set up in the preceding paragraph, it is well to refer to certain passages

* *The Utilities Magazine*, 1–3–113.

Mr. McCann.

of the report, wherein the strict reproduction theory is modified and violated in principle, and recourse is taken in effect to the original-cost method. Perusal of the report, moreover, would seem to indicate that the principles of a pure reproduction theory are adhered to whenever it is to the general advantage of the property under consideration, and that historical reproduction cost (another name for an enhanced original cost) is resorted to whenever the strict reproduction theory fails to give the "top-notch" figure, or fails to arrive at the known original cost.

The first specific example wherein the Committee recommends a departure from the strict reproduction theory, in favor of the historically modified reproduction theory, is found on pages 1363 to 1765 (inclusive) of the report. Here there are cited instances of three different dams and reservoirs which were built under entirely different circumstances respecting contingent and auxiliary costs. The Wachusett Reservoir required the obliteration of several buildings, highways, railroads, and other property formerly on the present reservoir site. The Kensico Dam, built within the limits of an existing reservoir, required the construction of two temporary reservoirs to maintain a water supply. The Au Sable Dams were constructed under simple circumstances, unaccompanied by exceptional costs of damages, removals, or temporary works. The Committee asks if it is fair, for the reasons stated, "to assume like conditions to govern the estimate of reproduction cost to be used as a basis of 'fair value' ".

It certainly is apparent that these three dams and reservoirs are not to be appraised under "like conditions." The strict reproduction theory, however, calls for an appraisal of the existing property as it is to-day. Such a premise is satisfactory, say, for the Au Sable Reservoir, which did not encounter any unusual auxiliary costs during its construction. The strict reproduction theory, however, will not produce sufficient value for the Kensico and the Wachusett Dams; therefore the Committee, following in the footsteps of experts who have forsaken and modified the strict reproduction theory, "is of the opinion that all such items of cost, due to damages, destruction of property, purchase of rights, and temporary works, as cited in these illustrations, are clearly proper items to be included in the reproduction estimate when capable of historic proof", and this despite the fact that original-cost appraisals of these dams would reveal, in a very few items, the exact total sums expended in each of the three works.

It is not amiss at this point to contrast the proposed historical reproduction method, advocated by the Committee, with the original-cost method defined hereinbefore. In the Wachusett Dam, for instance, the appraiser must make a complete survey of the dam and reservoir as it is to-day; then he must apply unit costs of labor and material

Mr. McCann.

at prevailing prices to-day. Thus, the appraiser derives the reproduction estimate of the existing structure, whereupon he starts to conjecture what may have happened during the years of construction. Imagination is brought into full play in picturing the day-by-day and month-by-month changes in the scenery before him—once an industrious valley, teeming with activity, possessing thriving railroads, and incrusted with dust from many roads, now simply a peaceful lake. Many things might have happened during this transformation, and therefore the appraiser is restrained in his imaginative process to what actually did happen. The records of the work must be consulted, inasmuch as fascinating conjectures must be proved before commissions and Courts. Should the appraiser wander very far from the recorded facts and the actual cost thereof, he is in difficulties, if a keen counsel cross-examines him thoroughly as to the details underlying his theory. How much simpler it is to set forth the book-recorded costs and quantities of a few principal items, such as clearing, sanitation, excavation, temporary works, construction camp, masonry, earth fill, spillway, moving structures, moving highways, moving railways, etc. In arriving at fair values, commissions and Courts are not in the habit of disallowing sums which have been prudently and wisely expended in the construction of used and useful utility property; instead, their problem is to isolate the reasonable from the limitless conjectures of experts and from the flowery arguments of attorneys who seek to inflate the much-abused term "value."

The remarks of the last paragraph apply equally well to several other specific examples set forth by the Committee. The instances of the Pennsylvania and New York Central Terminals, on page 1365, are very similar to the aforesaid dam examples. There is little doubt in the writer's mind that excellent cost data are available for the recently-constructed New York terminals. Why is it necessary to disregard the actual original cost of these terminals and turn to a conjectural reproduction thereof? Opponents to the reproduction theories will answer that the underlying reason lies in the possibility of claiming inequitable increments in the railway's capital account. Advocates of the reproduction theories will answer that the purpose is to arrive at present value; and then the deluge of arguments of what constitutes value soon creates mire sufficient to obscure the original issue.

The next example cited by the Committee is that of a certain highway crossing a railroad track. For the sake of brevity, the Committee's statement (page 1366) relating thereto is reproduced, as follows:

"One illustration brought to the attention of the Committee is a case of a highway which originally crossed a steam railroad at a very acute angle, making a dangerous crossing to both railroad and

Mr. McCann.

public. At its own expense the railroad acquired land parallel with its own, changed the course of the road for several hundred feet and made a right-angled crossing. It was argued that, 'in case of reproduction, all other property remaining as at present', the highway would be in its new location and would not have to be reproduced. On this basis, many items which the owner of a railroad or other public utility was compelled to pay for might be cut out of an appraisal. But the highway would be in its original place were it not for the act of the railroad, and would have to be moved by any railroad, building presently, if the existing road had not been built; the evidence of the necessity, however, having been destroyed in the doing. The cost was a proper cost, capable of historic proof; and the Committee believes that it should be included as a cost in the estimate of reproduction."

If the writer understands this last illustration correctly, the cost of the old highway crossing (which had grown inadequate to meet modern traffic condition, and was dangerous), should be charged against the railway's accrued depreciation fund, created for the purpose of replacing equipment, structures, and other property as it wears out, grows obsolescent, and becomes inadequate. The actual cost, borne by the railway, of the new and re-aligned highway crossing should be placed in the capital account of the carrier; and such an item would appear in simple terms in an original-cost appraisal, without theorization of what may have happened during a process of reproduction.

It seems needless to dwell further on the several instances wherein the Committee advises departure from the strict reproduction theory and recommends the historical modification thereof. The writer regrets that the Committee did not see fit, in each of the examples, to point out wherein the original-cost method would establish more convincing equities before a tribunal in a valuation proceedings.

Before leaving the Committee's specific examples of application of a reproduction theory, attention is called to the stone bridge piers, instanced on page 1373 of the report, and to similar examples following. Certain abutments of a railroad bridge, built of stone masonry at a cost-to-reproduce of from $12 to $16 per cu. yd., in accordance with the road's practice for the previous 10 years, would now be built with concrete at a cost of from $7 to $11 per cu. yd. The Committee's conclusion, as to this and similar examples, is that the precise existing structure should be appraised at its reproduction cost, and that the only departures (page 1374) from such a rule are the cases where, due to obsolescence of existing machinery, it is absolutely absurd to pursue this method to its ultimate conclusion. Once again comment is forthcoming to the effect that the Committee's recommendations result in an adherence to the strict reproduction theory whenever the value to be derived therefrom enhances the original cost of an item of property; but, if the strict theory does not establish sufficiently high values, it would seem that the Committee's idea is to modify the theory. If a

Mr. McCann.

theory can be modified in one place, there should be no great objection to a reasonable modification at another place. Unfortunately, multitudinous modifications of the strict theory result in individual theories of each and every appraiser. The writer, in the instance of the masonry abutments referred to, would call attention to the equities of appraisal at the original cost of the structure, regardless of what similar stone masonry is costing to-day, and regardless of the present-day cost of better concrete abutments.

Possibly it will not be amiss to cite here a pertinent criticism made by the late John M. Eshleman, formerly Lieutenant Governor of California, and once President of the California Railroad Commission, in an address* delivered before a conference held under the auspices of The Utilities Bureau, at Philadelphia, in November, 1915:

"* * *. The inconsistency of adopting the historical method with reference to some elements and rejecting it with reference to some others need only be mentioned. Why it is that the committee of presidents of the railroads of the United States should concern themselves with hidden costs of some elements of the properties of the railroads and forget all about hidden or other costs of lands and properties that have appreciated, is beyond my comprehension.

"I really seriously wonder at the logic of those who urge that cost shall ever have anything to do with this question unless they admit it has everything to do with it, and I marvel at their regard for the simplicity of public authority when they urge that original cost shall always be used even in their reproduction theory when it will give them more than present cost to reproduce, and at the same time utterly repudiate costs of lands and similar properties when such costs are less than the market value now obtained. I do not for a moment contend that the work of the engineers in making inventories, and, if you please, in fixing unit prices is not very important. But holding, as I do, that where government is dealing with monopoly it of necessity must deprive such monopoly of the power of taking all that it can get from its patrons, I am driven to conclude that government must determine as a substitute what the agency ought to take, and in determining what the agency ought to take, the safest and most just guide is what the agency has sacrificed and what service it has performed for the public. * * *"

That the original-cost method possesses merit in valuation proceedings is shown by such facts as (1) a more or less general adoption by regulatory State commissions of original-cost as a perfectly legitimate line of inquiry to shed light on property values, (2) the recognition by Congress of original cost as one of the methods to be pursued in the valuation of the nation's railroads, (3) the National Association of Railway Commissioners' unanimous insistence that original cost be considered in the Interstate Commerce Commission's valuation of common carriers' properties, and (4) Court decisions supporting the posi-

* *The Utilities Magazine*, 1-10-11.

Mr. McCann.

tion of the Supreme Court of the United States in Smyth *v.* Ames (cited by the Committee). No judicial authority, moreover, is to be cited to show that an estimate of the cost of reproducing the property (with or without deduction for accrued depreciation) is the sole and only guide to a reasonable and adequate valuation of a utility property for rate-making purposes. On the contrary, the inconsistencies of the reproduction method have been scored time and again. It is only recently that the Supreme Court of the United States, in the Des Moines Gas Case, repudiated the reproduction method when applied to what, in valuation work, is commonly termed "undisturbed paving."

In addition to those steadfast older commissions and their representatives, who have given due and just weight to the actual original-cost methods, it is noteworthy that many a recent author is outspoken in recommending the sacrifice of the investor as the measure of fair value, particularly fair value as a rate base. (Cf. Whitten and Hayes, *supra.*) A recent engineering contribution is "Public Utility Rates," by Mr. Harry Barker, Associate Editor of *Engineering News,* wherein the author (at pages 37 and 38) states:

"Present tendency seems to be to give more and more weight to figures of investment and investors' sacrifice in determining rate-basis worth. With the general imposition of proper accounting systems figures of investments and sacrifice can be more completely secured than in the past so that a better basis for value by investment can be established. Where regulation has been longest established, there investment has greatest weight; it is not unreasonable to expect that in the course of time the entire country may accept the theory. * * *"

The most common argument against the use of the original-cost method of valuing public utility properties, aside from the difficulties alleged to be encountered in securing records of such costs, is that appreciations in value of property (if such exist) are denied to the owners thereof. The reproductionists, however, do not point to any rule of common equity which entitles them first to earn an adequate return on their investments and then to participate in the profits which accrue to appreciation; but they rely on certain judicial passages, which in themselves are sound, although subject to linguistic abuses when applied unadvisedly to valuations that are made bases for rate schedules. Under certain rulings of the Courts, it may be argued that, even though a utility may steal equipment without being apprehended, and may convert that equipment into used and useful property in the service of the public, the stolen equipment must receive due recognition in a valuation and rate-making proceeding. Whether or not this view will prevail ultimately, under a continuance of State regulation, is a somewhat debatable question at the present time. A simple case will serve to illustrate the fallacy of too great weight given indiscriminately to appreciation in utility property. Assume that an electric plant, in a

Mr. McCann.

State where the laws provide for State regulation, costs $100 000, and assume, further, that the regulatory body of jurisdiction, after investigation at the very start, has fixed rates such as will yield full operating expenses plus 5% per annum ($5 000) for accruing depreciation and 7% per annum ($7 000) for a fair rate of return. At the end of 5 years, provided no change is made in the electric property, the utility will have accumulated $25 000 (plus earnings) in a depreciation fund, and each year will have paid a full and adequate rate of return on the entire investment. During these 5 years, if perchance the prices of labor and materials advance so that the estimated reproduction-cost-new of the identical property at the end of the period, according to expert appraisers, would be $110 000 (exclusive of betterments and additions), there will have been an unearned increment, over and above a fair rate of return, amounting to $10 000 in the value of the property—equivalent to $2 000 per year, or 2% annually on the original cost. In other words, a valuation thus made at the end of the said 5 years, resulting in revised rates being fixed on an estimated reproduction theory, capitalizes an unearned increment which automatically results in rendering a 9% rate of return throughout the entire first 5-year period. What has the utility done or denied to itself in order to deserve this unearned increment? Is not the public entitled to participate in the appreciation of property, at least to the extent of not having the same capitalized against it, to be borne by the rate-payers of the future? Carrying the illustration still further, let it be assumed that the estimated reproduction value sinks to $90 000 at the end of 5 years; then the reverse is true, and the utility each year is deprived of just earnings equivalent to 2% of the cost of the property. Under such conditions, would it not be argued that this deprivation of earnings would constitute a confiscation of property?

Such illustrations are indicative of the public's vital interest in what is termed "appreciation." It is to be borne in mind that "depreciation", as applied in valuation work, in no manner is the opposite of "appreciation." An original-cost valuation, if properly compiled, does not presume to inflict on a utility the losses occasioned by decreases in prices of material and labor. An original-cost valuation, however, does presume to reflect the conditions under which the bargain between a utility and its consumers was consummated. Under an original-cost valuation, the public sustains all losses due to the falling off of prices, although it participates in gains only to the extent of not having an unearned increment capitalized against it.

The reproduction theory has its place. It is undoubtedly one evidence of value, and an appraisal predicated on the strict reproduction theory should be made a part of every rate case; but the reproduction theory (or some modification thereof), under no circumstances, should be construed as the sole and only guide to value. Ultimate value for

Mr. McCann. rate-making purposes is a discretionary exercise of judgment on the part of those governmental agencies which are empowered by legislative enactment to regulate public utilities, subject of course to judicial review should the administrative power be abused.

The Courts have not ruled that reproduction-cost-new (or less depreciation) must be the criterion by which to judge the present value of utility property for rate-making purposes; neither have the Courts stated that such reproduction-cost-new (or less depreciation) is not to be used, nor that original cost is not to be used. What the Courts have said is that all these evidences of value are elements to be considered with other factors in fixing on value for rate-making purposes. Whenever reproduction advocates turn their attention to bringing forth the advantages of the original-cost method as earnestly as they have expounded the reproduction theory, the disadvantages of the reproduction theory, which make it necessary to resort to original conditions and to original-cost conceptions, will disappear miraculously in a strict adherence to the actual original cost method of valuation. A fair rate of return on the actual dollars prudently expended for utility property that is used in and useful to the rendering of public service are words that jingle with equity; and it is the writer's opinion that judicial sanction, supporting the position of commissions respecting original cost, is not long to be withheld.

Paper No. 1402

THE DISTRIBUTION OF STRESSES IN MITERING LOCK-GATES, WITH SPECIAL REFERENCE TO THE GATES ON THE PANAMA CANAL

BY HENRY GOLDMARK, M. AM. SOC. C. E.

SYNOPSIS.

This paper is based on an extended study of the laws which govern the distribution of stresses in different parts of a mitering lock-gate under service conditions. For reasons mentioned in the paper, the problem is indeterminate, so that the solution was based on the theory of elastic work.

A general method of computation is first outlined, which is simple in principle, though the computations are somewhat laborious. It is believed to be more complete and accurate than any previously developed.

An application to several of the lock-gates on the Panama Canal follows. The resultant loads which are sustained by the different horizontal girders and by the vertical bracing are computed in detail, as well as the pressures exerted by the gates against the bottom sills.

Some practical conclusions, drawn from the results obtained, are also given, as a guide for future designs.

General.

Mitering gates have been used in canal locks for several centuries, and are still the preferred form, to the virtual exclusion of other types. In large modern locks, they are generally built of steel, and are among the most expensive structures used in hydraulic works. In the interest of economy as well as safety, therefore, careful designing, based on a correct determination of the stresses, is a matter of importance.

The problem of finding the stresses in such gates is intricate, and has been the subject of much investigation in the past. In connection with the design of the gates for the Panama Canal, the largest yet built, the writer had occasion to make a rather detailed study of the subject. It seems proper to put on record some of the results obtained, especially as American literature on lock-gates is very scanty. It is believed that the method of calculation used is novel, and is an advance on previous practice.

The stresses are of two kinds, those due to the weight of the gate leaf, and those due to water pressure. The former do not affect the design of the gate seriously, except in the parts which serve to support it on the foundation, and to connect it to the anchorage in the walls. They are greatest when the lock chambers are emptied to permit of inspection and repairs. Their computation is quite simple when the weight of the metal work is known.

The stresses due to hydrostatic pressure, on the other hand, govern the dimensions of the principal members, as well as most of the secondary parts. The external loads in this case, too, are entirely definite, as well as their points of application, but the stresses they produce are somewhat indeterminate. This is due, in large part, to the complex structure of the leaf, which has numerous horizontal and vertical members riveted together at their intersections and covered by a continuous sheathing. The primary function of the different members, in transferring the hydrostatic load to the masonry, is well defined, but the rigid connections cause the deflection and, hence, the stress in any

one member to depend, not only on its direct load, but also on other parts of the gate.

The distribution of the stress, therefore, is complicated, even in single-leaf gates which span the lock at right angles and support the water pressure by beam action.

In miter-gates, which act as arches, there are further difficulties. The first arises from variations in the surface of contact on the miter and quoin-posts, where the gates bear against each other and against the hollow quoin. Especially if timber bearing pieces are used, the exact point at which the reaction acts, is uncertain, so that it is necessary, in the computations, to assume it to have a considerable deviation from the center of the bearing, in order to obtain the maximum stresses.

A further difficulty arises from uncertainty as to the pressure exerted by the gate against its sill. In single-leaf gates this will not change appreciably after the first adjustment is made. In miter-gates, however, there are wide variations in the sill reaction at different times, with corresponding changes in the stresses. This is due to changes in the length of the leaves arising from variations in temperature, wear in the contact pieces on the gate posts and sills, and from various minor causes. Even with careful workmanship and fitting, it is hardly possible to ascertain the sill pressure exactly, although, as will be shown later, it is feasible to arrive at limiting values, not likely to be exceeded in practice.

In this paper, a method of calculation is developed, by which the sill reaction and the loads on the different horizontal and vertical girders may be found in a given gate for an assumed hydrostatic loading and various conditions of sill contact. After these loads have been fixed, the stresses in the different members can be computed without special trouble. The gates are assumed to be of steel and "horizontally framed" with numerous horizontal girders. In the gate with "vertical framing", which has only two main horizontals, the stresses are more determinate, and the theory is much simpler.

The problem is first stated in general terms, and a solution is found applicable to gates of varying dimensions, girder spacing, and cross-sections. It is then applied to the largest and the smallest of the

Panama gates. Finally, some practical conclusions derived from the computations are given, as a guide in future designs.

Statement of Problem.—A mitering lock-gate consists of two leaves, which together support the water pressure due to the difference of head on the opposite sides of the gate.

If there is no contact at the bottom sill when the gate is closed and under pressure, the entire hydrostatic load is transferred by arch action to the side-walls. On the other hand, if the leaves bear against the sill, the latter will carry a part of the load, the remainder being, as before, supported by the lock walls.

The proportion of the total load which will go to the sill, in any given case, depends on the structural arrangement of the gate frame and the relative adjustment of the gate and sill.

The object of the investigation given herewith was to determine, for the Panama lock-gates, the pressure of the gates against the sills for different adjustments, the distribution of the loading between the several horizontal girders, and the stresses in the vertical framing.

Previous Investigations.—The determination of the laws which govern the distribution of loading in the horizontal and vertical members of mitering-gates has been made the subject of extended studies by several distinguished engineers in the past.

M. Chevallier* made what was perhaps the first study of this subject. It included a series of tests with wooden models. The conclusions he drew from his experiments, as to the interaction of horizontal and vertical members in gate leaves, are in entire accordance with subsequent investigations, and of much interest even now. He gave no general formulas or rules applicable to the large gates of modern times.

In 1867, M. Lavoinne† published a mathematical investigation covering the same subject. His method is very complicated, although applicable only to gates having equal horizontals spaced at equal vertical distances. Owing to these assumptions, and for other reasons, Lavoinne's formulas are not applicable to large modern gates, in which the cross-section and spacing vary from the top to the bottom of the leaf.

---

* *Annales des Ponts et Chaussées* for 1850.
† *Annales des Ponts et Chaussées.*

In 1887, M. Galliot* presented a new mathematical study, making practically the same assumptions as Lavoinne, but attaining somewhat simpler results.

In his treatise on "Mitering Lock Gates", published in 1892, First Lieut. (now Brig.-Gen.) H. F. Hodges, U. S. A., gave a discussion on vertical framing on a somewhat different basis, and deduced valuable rules for its practical dimensioning.

Method of Calculation Used in the Present Investigation.—The method herewith presented was developed by the writer in a less perfect form, in 1899, in a study on lock-gates made for the Board of Engineers on Deep Waterways.

The solution is based on the well-known "method of least work." It takes account of irregular spacing in the horizontal girders, as well as of variations in their cross-sections, and considers the cross-bending as well as the direct compression in the girders. In case timber is used for cushions at the miter and quoin posts, or at the sill, the formulas obtained can easily be modified, so as to allow for the difference of material.

Although the method is correct in theory, the unavoidable lack of homogeneity in the steel, the difficulty of determining the vertical and horizontal rigidity of the leaf exactly, still more the uncertainty as to the relative adjustment of the gate leaves and the sill, prevent a very close determination of the actual stresses.

It is believed, however, that the results obtained are reliable within reasonable limits, and will prove of much use in analyzing the strength and stiffness of existing gates or proposed designs. It should be added that the formulas when applied to the gates of the Poe Lock, at Sault Ste. Marie, gave results agreeing quite closely with deflection measurements made by the writer.

Like most applications of the elastic theory to complex structures, the method of least work cannot precede, but must follow, the complete design. In other words, it is necessary to adopt a detailed arrangement of all parts and afterward determine the distribution of the stresses in the different members.

Effect of Vertical Stiffness.—A gate leaf consisting only of a certain number of horizontal girders and an absolutely flexible sheathing would have no vertical stiffness. Such a gate would transfer no load

* *Annales des Ponts et Chaussées.*

to the sill, except the water pressure which acts on the lower half of the bottom panel and is carried directly to the sill by the sheathing. Each horizontal girder would support simply the load which corresponds to the hydrostatic head due to its position.

In practice it is impossible and undesirable to build a gate without vertical rigidity. The sheathing, combined with the quoin and miter posts and the intermediate vertical brace frames and intercostals, forms a vertical girder of considerable strength. By its resistance to bending, this girder modifies the loads on the different horizontals, making them greater or less than those corresponding to the hydrostatic pressure. As a rule, the vertical girder transfers a part of the total water pressure to the sill.

For purposes of calculation, the leaf is taken as consisting of a horizontal and a vertical system of girders crossing each other at right angles. The horizontal system consists of the several main girders or arches, spaced as they are in actual construction. The vertical system is assumed to be equivalent to a single girder extending continuously over the whole length of the leaf from the quoin to the miter post. Its flanges are formed by the gate sheathing, and its web is equivalent in total cross-section to the web plates in the several vertical frames and end posts. This simplification is justified by the close spacing of the vertical frames and intercostals, which prevents the skin plates from buckling.

Sill Contact.—In case there is no contact at the sill, even when full water pressure acts, the entire load, of course, will be carried by the horizontal arches to the side-walls.

If, in such a gate, all the horizontals are proportioned to support the hydrostatic head with exactly the same unit stresses in the steel, they will all have exactly the same deformations under load. There will be no bending stress in the vertical girder, so that it will remain straight, even after the gate is supporting the water pressure. The loads on the several horizontals will be those corresponding to their hydrostatic head.

In practice, the horizontals near the top are always stronger than theory requires, in order to ensure increased safety against accidental blows and to avoid the use of unduly small rolled shapes. It is also hardly possible to design all the other horizontals so that they shall sustain exactly the same unit stresses. There will always be some

variation, therefore, in the deflections of the different horizontal girders. This will produce a tendency to bend the vertical girder which is rigidly connected to the horizontals, and its resistance to bending, in turn, will affect the deflections and modify the loads of the horizontal frames.

However, the effect of vertical rigidity, when there is no sill contact, will be very small, except at the extreme top of the leaf.

The case of "no contact" should always be provided for in the design, for, from various causes, it is likely to occur in all mitering lock-gates as either a temporary or permanent condition.

In ordinary cases there will always be a greater or less reaction at the sill. If the water on the up-stream side extends to the top of the gate, and there is no lower pool, the greatest sill pressure theoretically possible would be equal to two-thirds of the total load supported by the gate. This maximum can only occur when the adjustment is so inaccurate that, even with continuous contact along the sill, the two leaves will touch only at the very top of the miter posts, even when the gate is subjected to the full head of water. This is an extreme case which would seriously overstrain the gate, and can be avoided by ordinary care in adjusting the leaves and sill.

A much smaller reaction may be counted on as a practical maximum. It seems quite safe to assume what is sometimes called "perfect contact", that is, continuous contact along the quoin and miter posts and also along the sill when the gate is closed, but before it is subjected to water pressure.

With both timber and metallic bearings, the actual conditions will probably correspond to lower sill pressures, as there will rarely be absolute sill contact in the dry.

Therefore, two conditions of adjustment at the sill were considered in the computations:

(1) No contact at the sill, even with full head;
(2) Simultaneous contact at the sill, miter, and quoin posts, before the water pressure is applied.

Let Fig. 1 represent the vertical section and Fig. 2 the plan of a gate leaf, of length, L, consisting of $(n + 1)$ horizontal arches and a continuous vertical girder, the stiffness of which is assumed to be uniformly distributed over the length of the leaf. The sheathing is

supposed to carry the water pressure directly to the horizontals, and the connections to be such as to permit the transference of horizontal reactions between the arches and the vertical girder at their intersections. Let the magnitude of these reactions be denoted by X_0, X_1, ... X_n per linear horizontal unit of leaf. They will be both positive and negative in direction, and will act normally against the arches exactly as water pressure does.

If, further, P_0, P_1, ... P_n, are the direct water loads on the several arches per linear unit, their resultant total loads will be:

$$(P_0 + X_0)\ L\ (P_1 + X_1)\ L\ .\ .\ .\ .\ (P_n + X_n)\ L.$$

With no contact at the sill, all these loads are carried by arch action to the hollow quoins; but, if the lowest arch bears against an absolutely fixed sill, that arch will carry no load to the side-wall, and $(P_n + X_n)\ L$ will become the sill reaction.

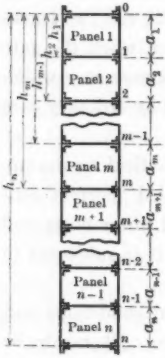

FIG. 1.

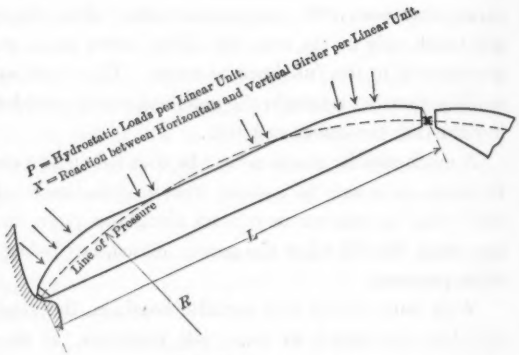

FIG. 2.

In any case the only forces acting on the vertical girder will be the transverse loads,

$$X_0\ L,\ X_1\ L, \ldots X_n\ L.$$

The static conditions of equilibrium as applied to this girder give only two equations:

$$\Sigma\ X = X_0 + X_1 + \ldots . X_{n-1} + X_0 = 0 \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

$$\Sigma\ M = X_0\ h_n + X_1\ (h_n - h_1) + \ldots X_{n-1}\ (h_n - h_{n-1}) = 0 \ldots . (2)$$

for determining the values of X_0 . . . X_n, although there are always at least three such unknown quantities.

Similarly, if the gate as a whole is considered, the reactions of the horizontals against the side-walls are indeterminate, as their number is in excess of the number of equations which can be obtained from static conditions.

The stresses in indeterminate structures of this kind, however, can be found by an application of the method of least work. The principle on which this depends may be briefly explained as follows:

If a perfectly elastic structure is subjected to external forces, the fibers in its parts will be deformed until a new condition of equilibrium is reached. The work done in this deformation (the internal work or elastic potential) will always be equal in amount to the external work, that is, the work done by the external forces.

By the principle of least work, the reactions and internal stresses corresponding to the new condition of equilibrium, in addition to being consistent with the statical equations, must be such as will make the total internal work done by the structure, in passing from its original to its new condition, a minimum.

This principle is sometimes derived from the theory of virtual displacements, but may almost be considered axiomatic, representing the theory of equilibrium in its most general form as applied to elastic solids.

The application of the method of least work to this problem consists in stating the work of internal deformation in terms of the known external loads and the indeterminate quantities X_0, X_1 . . . X_n, and finding those values of the latter, which, besides satisfying the static Equations (1) and (2), will give a minimum value for the total internal work done, while the gate passes from a condition of no stress to that in which the full water pressure is supported.

The internal work in the whole leaf will consist of the following parts:

(1) That due to arch action in the horizontal girders, involving generally both direct compression and cross-bending; and
(2) The work of bending the vertical girder.

The work done as the result of the shearing stresses in the arches and the stresses in the web members of the vertical girder, being relatively quite small, may be neglected.

The bending in the horizontal girders is due to the eccentricity of the line of pressures or resultants with reference to the center of gravity at the different cross-sections. For arches with continuous curvature, this eccentricity is quite small, but occurs to some extent in all gates.

If U_h = the internal work in the horizontal, and U_v that in the vertical girders, then,

$$U = U_h + U_v \text{ is the total internal work.}$$

For any elastic solid under purely axial stress (that is, direct compression or tension), the work of deformation will be:

$$U_s = \int_0^L \frac{T^2}{2\,E\,F}\,d\,l \qquad (3)$$

and, for one subject to cross-bending only (beam action),

$$U_b = \int_0^L \frac{M^2}{2\,E\,I}\,d\,l \qquad (4)$$

in which equations:

L = the total length of the member;

F and I = the cross-sections and moments of inertia at any point;

E = the modulus of elasticity; and,

T and M = the total axial force and bending moment at any cross-section.

From Equations (3) and (4) a general expression for the work equation for all parts of a mitering lock-gate (such as is shown in Fig. 1) may be written:

$$U = \sum_{m=0}^{m=n}\left[\int_0^L \frac{T_m^{\,2}}{2E\,F_m}\,d\,l + \int_0^L \frac{M_{hm}^{\,2}}{2\,E\,I_{hm}}\,d\,l\right] + \sum_{m=1}^{m=n}\int_0^{a_m} \frac{M_{vm}^{\,2}}{2\,E\,I_{vm}}\,d\,l \qquad (5)$$

In this equation, m corresponds to any horizontal arch and also to the panel of the vertical girder just above the arch so denoted. The axial thrust and bending moment at any point in a horizontal are represented by T_m and M_{hm}, respectively; and M_{vm} is the bending moment at any point in the vertical girder. The first two terms give U_h (work in all horizontal arches), the integration being for the length of each individual arch and the summation to include the

$(n + 1)$ different arches. The last term gives U_v (work in vertical girder), the integration being for each separate panel, while the summation includes all of them.

The cross-sections, F_m, and the moments of inertia, I_{hm} are the average values for any given arch, and I_{vm} is taken as uniform for any given panel of the vertical girder.

As will be shown later, T_m, M_{hm}, and M_{vm}, and, hence, U (Equation 5) may be readily expressed in terms of the indeterminates, $X_0 \ldots X_n$, and the known quantities. If, in the resulting equation, the condition of statical equilibrium is introduced by putting, for X_n and X_{n-1}, their values in terms of the other $(n - 1)$ variables (using Equations 1 and 2), U will be expressed as a function of $X_0 \ldots X_{n-2}$.

Differentiating under the integral sign, we readily obtain the $(n - 1)$ partial derivatives required for finding those values of X which, consistent with statical equilibrium, will make the elastic potential a minimum. Using the same notation as before, they will be:

$$\left.\begin{aligned}
\frac{\delta U}{\delta X_4} &= \sum_{m=0}^{m=n}\left[\int_0^L \frac{T_m \delta T_m}{E F_m \delta X_0} d l + \int_0^L \frac{M_{hm} \delta M_{hm}}{E I_{hm} \delta X_0} d l\right] \\
&\quad + \sum_{m=1}^{m=n} \int_0^{a_m} \frac{M_{vm} \delta M_{vm}}{E I_{vm} \delta X_0} d y = 0 \\
\frac{\delta U}{\delta X_1} &= \sum_{m=0}^{m=n}\left[\int_0^L \frac{T_m \delta T_m}{E F_m \delta X_1} d l + \int_0^L \frac{M_{hm} \delta M_{hm}}{E I_{hm} \delta X_1} d l\right] \\
&\quad + \sum_{m=1}^{m=n} \int_0^{a_m} \frac{M_{vm} \delta M_{vm}}{E I_{vm} \delta X_1} d y = 0 \\
&\cdots \\
\frac{\delta U}{\delta X_{n-2}} &= \sum_{m=0}^{m=n}\left[\int_0^L \frac{T_m \delta T_m}{E F_m \delta X_{n-2}} d l + \int_0^L \frac{M_{hm} \delta M_{hm}}{E I_{hm} \delta X_{n-2}} d l\right] \\
&\quad + \sum_{m=1}^{m=n} \int_0^{a_m} \frac{M_{vm} \delta M_{vm}}{E I_{vm} \delta X_{n-2}} d y = 0
\end{aligned}\right\} \ldots (6)$$

In Equations (6) the first two terms correspond to the work done in the horizontal arches, and the last term to that in the vertical girder, so that these equations are of the form:

$$\frac{\delta U}{\delta X} = \frac{\delta U_h}{\delta X} + \frac{\delta U_v}{\delta X} = 0 \ldots \ldots \ldots \ldots \ldots (7)$$

The direct thrust, T, in a lock-gate is nearly constant throughout the length of the leaf for any given horizontal girder, and may be expressed very simply.

If r = the radius of a circle which passes through the centers of bearings at the quoin and miter posts when the gate is closed (Fig. 2); and

P = the load per linear unit on the horizontal girder; then

$T = P\,r$.

For any horizontal frame, m, in a gate, therefore, we can write,

$$T_m = (P_m + X_m)r \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

Also, if e_m is the mean eccentricity of the resultant in the horizontal girder, m, that is, the average distance between the line of pressures and the center of gravity of the cross-section, we can also write,

$$M_{hm} = e_m T_m = (P_m + X_m)\, e_m\, r \ldots\ldots\ldots\ldots\ldots (9)$$

The first two terms in Equations (6), which correspond to the work in the horizontal arches, therefore, may be written in the form:

$$\frac{\delta\, U_h}{\delta\, X} = r^2 \sum_{m=0}^{m=n} \frac{1}{E}\left[\frac{1}{F_m} + \frac{e_m^{\,2}}{I_{hm}}\right] \int_0^L \frac{(P_m + X_m)\,\delta\,(P_m + X_m)}{\delta\, X}\, d\,l \ldots (10)$$

Similarly, the last term of Equations (6) and (7), corresponding to work in the vertical girder, may be easily expressed as follows:

Let M_{vm} be the bending moment in any point at any panel, m, and let the distance of this point below the panel point next above $= y$. We can then write,

$$M_{vm} = L[(h_{m-1} + y)\, X_0 + (h_{m-1} - h_1 + y)\, X_1 + \\ \ldots + (h_{m-1} - h_{m-2} + y)\, X_{m-2} + y\, X_{m-1}] \ldots\ldots (11)$$

The partial derivatives will be,

$$\frac{\delta\, M_{vm}}{\delta\, X_0} = L\,(h_{m-1} + y), \quad \frac{\delta\, M_{vm}}{\delta\, X_1} = L\,(h_{m-1} - h_1 + y)$$

$$\ldots \quad \frac{\delta\, M_{vm}}{\delta\, X_{m-1}} = L\, y.$$

That portion of the last term in Equations (6) which corresponds to the work in Panels (1) to $(n-1)$ will then be given by the following expression:

$$\sum_{m=1}^{m=n-1} \int_0^{a_m} \frac{M_{vm}\,\delta\,M_{vm}}{E\,I_{vm}\,\delta\,X_0}\,d\,y$$

$$= \sum_{m=1}^{m=n-1} \frac{L^2}{E\,I_{vm}} \left[\left\{ h^2_{m-1}\,a_m + 2\,h_{m-1}\,\frac{a_m^2}{2} + \frac{a_m^3}{3} \right\} X_0 \right.$$

$$+ \left\{ h_{m-1}\,(h_{m-1} - h_1)\,a_m + (2\,h_{m-1} - h_1)\frac{a_m^2}{2} + \frac{a_m^3}{3} \right\} X_1$$

$$\left. + \quad . \quad . \quad . \quad + \left\{ h_{m-1}\,\frac{a_m^2}{2} + \frac{a_m^3}{3} \right\} X_{m-1} \right] \quad \ldots\ldots\ldots (12)$$

and there will be similar forms corresponding to the other variables, $X_1 \quad . \quad . \quad . \quad X_{n-2}$.

The part of the last term of Equations (6) corresponding to the work in the bottom panel must be obtained in a somewhat different way, as it is necessary to express X_n and X_{n-1} in terms of $X_0 \ldots X_{n-2}$.

Let z = the distance of any point in the panel from the bottom of the gate; then we can write:

$$M_{vn} = L\,z\,X_n$$

From Equations (1) and (2), if we take moments about the girder, $(n-1)$,

$$X_n = \frac{1}{a_n} \left\{ h_{n-1}\,X_0 + (h_{n-1} - h_1)\,X_1 \right.$$

$$\left. + \quad . \quad . \quad . \quad (h_{n-1} - h_{n-2})\,X_{n-2} \right\}$$

hence,

$$M_{vn} + \frac{L\,z}{a_n} \left\{ h_{n-1}\,X_0 + (h_{n-1} - h_1)\,X_1 \right.$$

$$\left. + \quad . \quad . \quad . \quad (h_{n-1} - h_{n-2})\,X_{n-2} \right\} \quad \ldots\ldots\ldots\ldots\ldots (13)$$

for which we readily derive,

$$\int_0^{a_n} \frac{M_{vn}\,\delta\,M_{vn}}{E\,I_{vn}\,\delta\,X_0} = \frac{L^2\,a_n}{3\,E\,I_{vn}} [h^2_{n-1}\,X_0 + h_{n-1}\,(h_{n-1} - h_1)\,X_1$$

$$+ \quad . \quad . \quad . \quad h_{n-1}\,(h_{n-1} - h_{n-2})\,X_{n-2}] \quad \ldots\ldots\ldots (14)$$

which represents the term corresponding to work in the bottom panel of the vertical girder. We can readily obtain similar forms when $X \quad . \quad . \quad . \quad X_{n-2}$ are the variables.

General Equations of Condition.—Combining Equations (10), (12), and (13), and omitting the common factor, $\frac{1}{E}$, we have the following general equations.

With X_0 as the independent variable:

$$\begin{aligned}
\frac{\delta U}{\delta X_0} &= r^2 \sum_{m=0}^{m=n} \left[\frac{1}{F_m} + \frac{e^2{}_m}{I_{hm}}\right] \int_0^L \frac{(P_m + X_m)\,\delta\,(P_m + X_m)}{\delta X_0}\, d\,l \\
&+ L^2 \sum_{m=1}^{m=n-1} \frac{1}{I_{vm}} \Big[\Big\{ h^2{}_{m-1}\, a_m + 2\, h_{m-1} \frac{a_m{}^2}{2} + \frac{a_m{}^3}{3} \Big\} X_0 \\
&+ \Big\{ h_{m-1}\,(h_{m-1} - h_1)\, a_m + (2\, h_{m-1} - h_1) \frac{a_m{}^2}{2} + \frac{a_m{}^3}{3} \Big\} X_1 \\
&+ \ . \ . \ . \ + \Big\{ h_{m-1} \frac{a_m{}^2}{2} + \frac{a_m{}^3}{3} \Big\} X_{m-1} \Big] \\
&+ \frac{L^2\, a_n}{3\, I_{vn}} [h^2{}_{n-1}\, X_0 + h_{n-1}\,(h_{n-1} - h_1)\, X_1 \\
&+ \ . \ . \ . \ + h_{n-1}\,(h_{n-1} - h_{n-2})\, X_{n-2}] = 0
\end{aligned}$$

and with X_1 as the independent variable:

$$\begin{aligned}
\frac{\delta U}{\delta X_1} &= r^2 \sum_{m=0}^{m=n} \left[\frac{1}{F_m} + \frac{e_m{}^2}{I_{hm}}\right] \int_0^L \frac{(P_m + X_m)\,\delta\,(P_m + X_m)}{\delta X_1}\, d\,l \\
&+ L^2 \sum_{m=1}^{m=n-1} \frac{1}{I_{vm}} \Big[\Big\{ h_{m-1}\,(h_{m-1} - h_1)\, a_m \\
&+ (2\, h_{m-1} - h_1) \frac{a_m{}^2}{2} + \frac{a_m{}^3}{3} \Big\} X_0 \\
&+ \Big\{ (h_{m-1} - h_1)^2\, a_m + 2\,(h_{m-1} - h_1) \frac{a_m{}^2}{2} + \frac{a_m{}^3}{3} \Big\} X_1 + \ . \ . \\
&+ \Big\{ (h_{m-1} - h_1) \frac{a_m{}^2}{2} + \frac{a_m{}^3}{3} \Big\} X_{m-1} \Big] \\
&+ \frac{L^2\, a_n}{3\, I_{vn}} [(h_{n-1} - h_1)^2\, X_1 + \ . \ \ . \ \ . + (h_{n-1} - h_1) \\
&(h_{n-1} - h_{n-2})\, X_{n-2}] = 0
\end{aligned} \qquad \ldots (15)$$

and equations of similar form for $X_2 \ . \ . \ . \ X_{n-2}$ as independent variables.

By making the proper substitutions and summations in Equations (15), the $(n - 2)$ simultaneous equations may be written, and from these, the values, X_1 to X_{n-1}, are readily found.

APPLICATION OF FORMULAS TO GATES OF THE PANAMA CANAL.

77½-Foot Gate.—The general arrangement of the gate leaf is shown on Plate XVI and the photograph, Fig. 3, which represents a somewhat lower gate before the sheathing is attached.

The principal dimensions are as follows:

Clear width of lock = 110 ft.;

Height of gate = 77 ft. 6 in. from top of coping to center of bottom girder;

Central thickness = 7 ft. 0 in.;

Shape of gate: straight-backed.

There are sixteen horizontals, the spacing of which is shown on Plate XVI and Fig. 1 of Plate XVII, and is tabulated subsequently.

The cross-sections, moments of inertia, and eccentricities of lines of pressures, which are shown on Fig. 1, Plate XVII, and are also given later, are mean values for each of the horizontal arches. The moments of inertia for the vertical girder are calculated from the skin thickness of each panel and the average depth of the girder. If t_1 and t_2 are the thicknesses of the up-stream and down-stream sheathing, and d_1 and d_2 their distances from the center of gravity of the cross-sections of the girder, the moment of inertia is given by the expression:

$$I_v = L(t_1 d_1^2 + t_2 d_2^2).$$

Summarized, the data are as follows:

Length of leaf, $L = 787$ in.,

Radius of line of pressures, $r = 880$ in. (See Plate XVII. Fig. 5.)

Horizontal Arches.—Mean cross-sections:

$F_0 = F_1 = F_2 = F_3 \ldots\ldots = 100$ sq. in.
$F_4 = F_5 \ldots\ldots = 120$ " "
$F_6 = F_7 = F_{15} \ldots\ldots = 140$ " "
$F_8 = F_9 \ldots\ldots = 164$ " "
$F_{10} = F_{11} = F_{12} = F_{13} = F_{14} \ldots\ldots = 200$ " "

Mean moments of inertia:

$I_0 = I_1 = I_2 = I_3 \ldots\ldots = 120\,000$ in.^{4}
$I_4 = I_5 \ldots\ldots = 140\,000$ "
$I_6 = I_7 = I_{15} \ldots\ldots = 156\,000$ "
$I_8 = I_9 \ldots\ldots = 167\,000$ "
$I_{10} = I_{11} = I_{12} = I_{13} = I_{14} \ldots\ldots = 190\,000$ "

Mean eccentricity of line of pressure:

$e_0 = e_1 = e_2 = e_3 \ldots = 26$ in.
$e_4 = e_5 \ldots = 21$ "
$e_6 = e_7 = e_{15} \ldots = 16$ "
$e_8 = e_9 \ldots = 13$ "
$e_{10} = e_{11} = e_{12} = e_{13} = e_{14} \ldots = 11$ "

Vertical Girder.—Moments of inertia:

$I_1 = I_2 = I_3 \ldots = 1\,100\,000$ in.^{4}
$I_4 = I_5 \ldots = 1\,180\,000$ "
$I_6 = I_7 \ldots = 1\,240\,000$ "
$I_8 = I_9 = I_{10} = I_{11} \ldots = 1\,400\,000$ "
$I_{12} = I_{13} \ldots = 1\,580\,000$ "
$I_{14} = I_{15} \ldots = 1\,720\,000$ "

Vertical Panels.—

$a_1 = a_2 = a_3 = a_4 \ldots = 66$ in.
$a_5 = a_6 = a_7 = a_8 = a_9 = a_{10} = a_{11} = 60$ "
$a_{12} = a_{13} = a_{14} = a_{15} \ldots = 54$ "

Heights.—

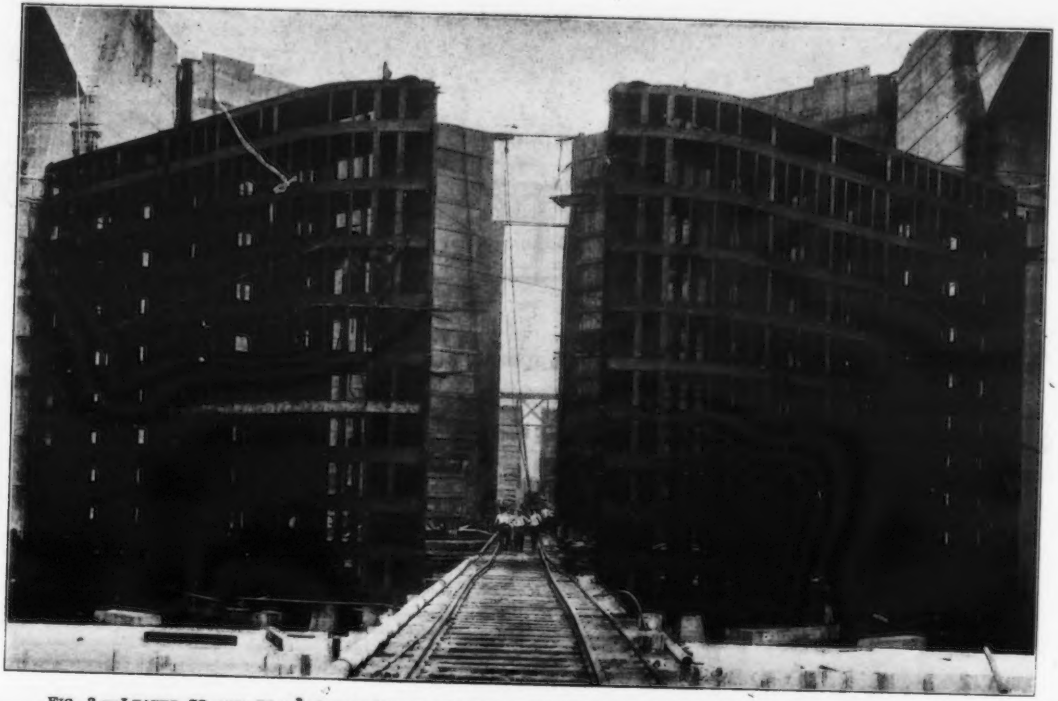
$h_1 = 66$ in.	$h_6 = 384$ in.	$h_{11} = 684$ in.
$h_2 = 132$ "	$h_7 = 444$ "	$h_{12} = 738$ "
$h_3 = 198$ "	$h_8 = 504$ "	$h_{13} = 792$ "
$h_4 = 264$ "	$h_9 = 564$ "	$h_{14} = 846$ "
$h_5 = 324$ "	$h_{10} = 624$ "	$h_{15} = 900$ "

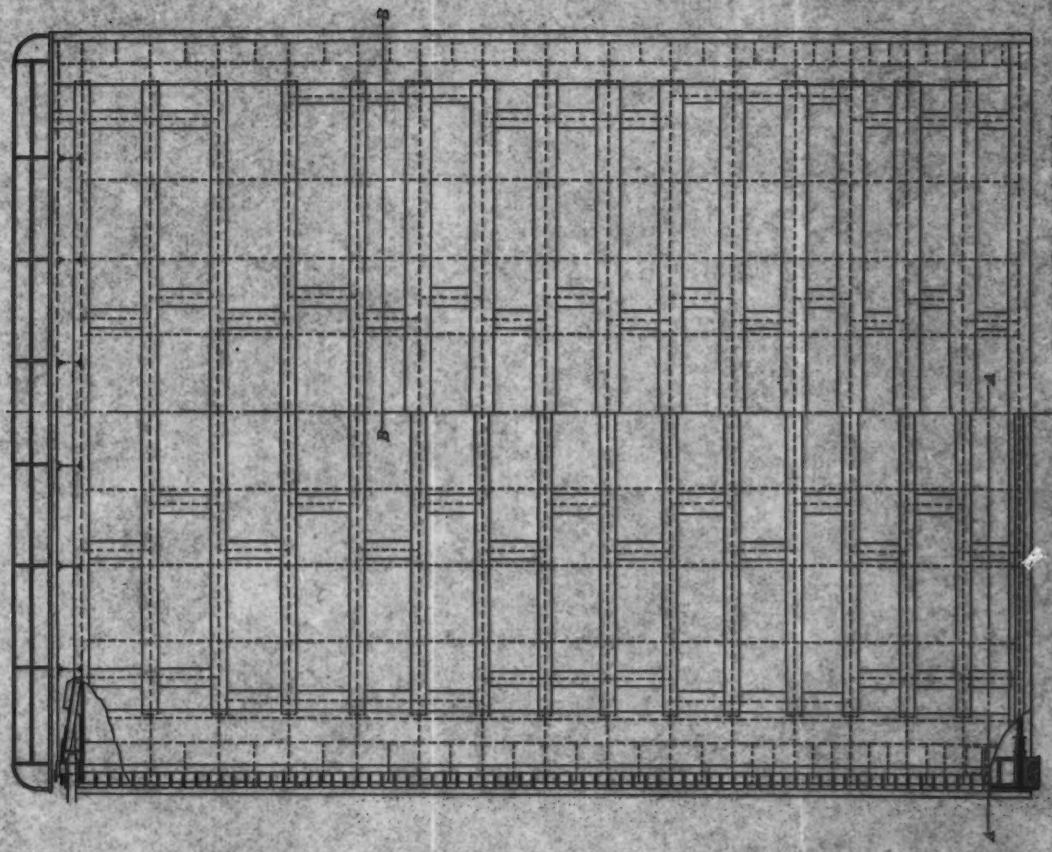
Water Pressure.—The water is assumed to extend to the top of the coping on the up-stream side of the gate, with a pool 9 ft. 6 in. deep below. Fig. 1, Plate XVII, shows the total water pressure and Fig. 2, Column *C*, of that plate, the load per linear foot on each horizontal arch.

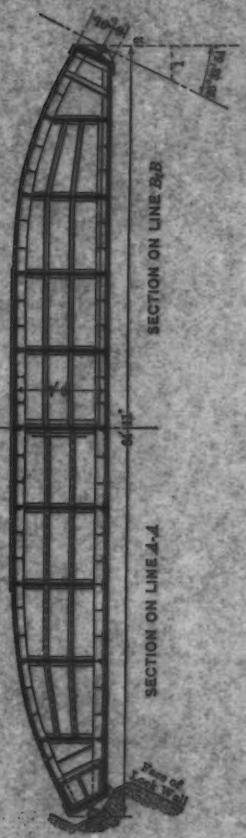
Reduced to the linear inch of girder, these values are:

$p_0 = 73.34$ lb.	$p_5 = 768.25$ lb.	$p_{10} = 1\,419.35$ lb.
$p_1 = 229.15$ "	$p_6 = 898.45$ "	$p_{11} = 1\,467.9$ "
$p_2 = 386.67$ "	$p_7 = 1\,028.65$ "	$p_{12} = 1\,500$ "
$p_3 = 544.13$ "	$p_8 = 1\,158.9$ "	$p_{13} = 1\,580.7$ "
$p_4 = 665.38$ "	$p_9 = 1\,289.$ "	$p_{14} = 1\,593.75$ "
		$p_{15} = 796.87$ "

FIG. 3.—LEAVES 72 AND 73 OF PEDRO MIGUEL LOCK, PANAMA CANAL. LEAVES 68 AND 69 IN THE BACKGROUND.







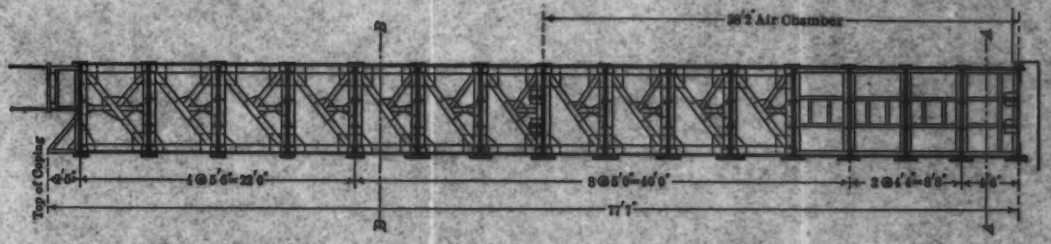


FIG. 3.—LEAVES 72 AND 73 OF PEDRO MIGUEL LOCK, PANAMA CANAL. LEAVES 68 AND 69 IN THE BACKGROUND.

PLATE XVI.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXXI, No. 1402.
GOLDMARK ON
PANAMA LOCK GATES.

The conditions of static equilibrium, as applied to the vertical girder, become:

$$X_{15} = -(X_0 + X_1 + X_2 + X_3 + X_4 + X_5 + X_6 + X_7 + X_8 + X_9 + X_{10} + X_{11} + X_{12} + X_{13} + X_{14}) \quad \ldots\ldots\ldots\ldots (16)$$

and,

$$X_{14} = -\frac{1}{54}(900\,X_0 + 834\,X_1 + 768\,X_2 + 702\,X_3 + 636\,X_4 + 576\,X_5 + 516\,X_6 + 456\,X_7 + 396\,X_8 + 336\,X_9 + 276\,X_{10} + 216\,X_{11} + 162\,X_{12} + 108\,X_{13})$$

whence,

$$X_{14} = -(16.66\,X_0 + 15.44\,X_1 + 14.22\,X_2 + 13\,X_3 + 11.78\,X_4 + 10.67\,X_5 + 9.56\,X_6 + 8.44\,X_7 + 7.33\,X_8 + 6.22\,X_9 + 5.11\,X_{10} + 4\,X_{11} + 3\,X_{12} + 2\,X_{13}) \quad \ldots\ldots\ldots\ldots (17)$$

and,

$$X_{15} = +15.66\,X_0 + 14.44\,X_1 + 13.22\,X_2 + 12\,X_3 + 10.78\,X_4 + 9.67\,X_5 + 8.56\,X_6 + 7.44\,X_7 + 6.33\,X_8 + 5.22\,X_9 + 4.11\,X_{10} + 3\,X_{11} + 2\,X_{12} + X_{13} \quad \ldots\ldots\ldots\ldots (18)$$

In order to introduce the static conditions of equilibrium, the values of X_{14} and X_{15}, in terms of $X_0 \ldots X_{13}$, as given in Equations (17) and (18), will be used as shown below.

The resulting simultaneous equations of condition, corresponding to $\frac{\delta U}{\delta X_0} = 0$, $\frac{\delta U}{\delta X_1} = 0$, etc., will then be reduced to fourteen, with $X_0 \ldots X_{13}$ as variables.

Work of Horizontal Arches.

The first terms of Equations (15) correspond to the total work of the horizontals.

Each arch must be taken up separately, and the values of the expression, $r^2\left(\frac{1}{F_m} + \frac{e^2_m}{I_{hm}}\right)\int_0^L (P_m + X_m)\frac{\delta\,(P_m + X_m)}{\delta\,X} d\,l$, obtained, taking $X \ldots X_{13}$, successively as variables. It may be convenient to represent this expression generally by the symbol H. Its values for the separate arches and variables will be the following:

Arch 0:

X_0 as variable:

$$H = 12\,106\int_0^L (P_0 + X_0)\frac{\delta\,(P_0 + X_0)\,d\,l}{\delta\,X_0} = 12\,106\,(P_0 + X_0)\,L$$
$$= 12\,106\,(78.34 + X_0)\,L = (12\,106\,X_0 + 948\,384)\,L$$

X_1 as variable:

$$H = 12\,106 \int_0^L (P_0 + X_0) \frac{\delta\,(P_0 + X_0)\,d\,l}{\delta\,X_1} = 0$$

and, similarly, we should find that $H = 0$ when $X_2 \ldots X_{13}$ are the variables.

Arch 1:

X_0 as variable:

$$H = 12\,106 \int_0^L (P_1 + X_1) \frac{\delta\,(P_1 + X_1)\,d\,l}{\delta\,X_0} = 0$$

X_1 as variable:

$$H = 12\,106 \int_0^L (P_1 + X_1) \frac{\delta\,(P_1 + X_1)\,d\,l}{\delta\,X_1} = 12\,106\,(229.15 + X_1)\,L$$
$$= (12\,106\,X_1 + 2\,774\,090)\,L.$$

For $X_2 \ldots X_{13}$, $H = 0$.

In like manner, for the arches, 3, 4 . . . 13, H will $= 0$ for every variable but one in the case of each arch. There will be a significant value, however, in the case of each arch for the one variable which has the same number as the arch in question.

These values of $H = r^2 \left(\frac{1}{F} + \frac{e^2}{I_h}\right) \int_0^L (P + X) \frac{(P + X)}{X}\,d\,l$ will be the following:

Arch 0.—X_0 as independent variable;	$H =$	12 106 X_0	+ 948 384
Arch 1.—X_1 " " "	$H =$	12 106 X_1	+ 2 774 090
Arch 2.—X_2 " " "	$H =$	12 106 X_2	+ 4 681 027
Arch 3.—X_3 " " "	$H =$	12 106 X_3	+ 6 587 238
Arch 4.—X_4 " " "	$H =$	8 892 X_4	+ 5 916 559
Arch 5.—X_5 " " "	$H =$	8 892 X_5	+ 6 831 279
Arch 6.—X_6 " " "	$H =$	6 802 X_6	+ 6 111 257
Arch 7.—X_7 " " "	$H =$	6 802 X_7	+ 6 996 877
Arch 8.—X_8 " " "	$H =$	5 477 X_8	+ 6 347 295
Arch 9.—X_9 " " "	$H =$	5 477 X_9	+ 7 059 853
Arch 10.—X_{10} " " "	$H =$	4 365 X_{10}	+ 6 195 463
Arch 11.—X_{11} " " "	$H =$	4 365 X_{11}	+ 6 407 383
Arch 12.—X_{12} " " "	$H =$	4 365 X_{12}	+ 6 547 500
Arch 13.—X_{13} " " "	$H =$	4 365 X_{13}	+ 6 899 755

Arch 14.—For this arch, the general form of H will be

$$H = 4\,365 \int_0^L (P_{14} + X_{14}) \frac{\delta\,(P_{14} + X_{14})}{\delta\,X}\,dl$$
$$= 4\,365 \int_0^L (1\,593.75 + X_{14}) \frac{\delta\,(1\,593.75 + X_{14})}{\delta\,X}\,dl$$

FIG. 4.

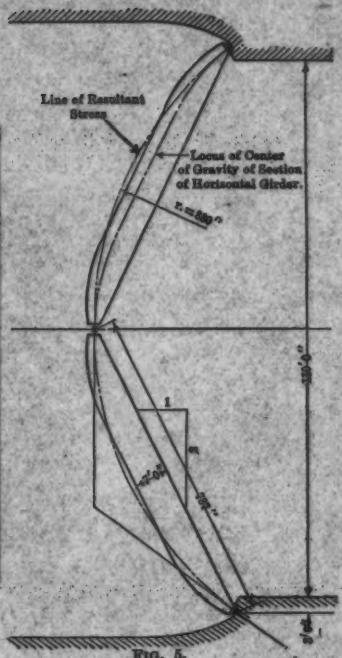

FIG. 5.

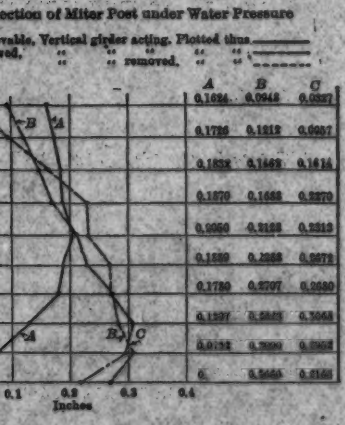

FIG. 9.

Substituting for X_{14} its value from Equation (17), we have

$$H = 4\,365 \int_0^L (1\,593.75 - 16.66\,X_0 \ . \ . \ . \ - 2\,X_{13}) \left[\frac{1}{\delta X}\delta\,(1\,593.75 - 16.66\,X_0 \ . \ . \ . \ - 2\,X_{13})\right] d\,l.$$

For the different independent variables, we have then total values for H:

X_0 as variable:

$$H = 4\,365\ (-16.66)\ (1\,593.75 - 16.66\,X_0 \ . \ . \ . \ - 2\,X_{13})\ L = (-115\,898\,930 + 1\,211\,500\,X_0 + 1\,122\,800\,X_1 + 1\,034\,000\,X_2 + 945\,370\,X_3 + 856\,650\,X_4 + 775\,900\,X_5 + 694\,920\,X_6 + 614\,100\,X_7 + 533\,330\,X_8 + 452\,500\,X_9 + 371\,700\,X_{10} + 290\,883\,X_{11} + 218\,163\,X_{12} + 145\,400\,X_{13})\,L$$

X_1 as variable:

$$H = 4\,365\ (-15.44)\ (1\,593.75 - 16.66\,X_0 \ . \ . \ . \ - 2\,X_{13})\ L = (-107\,411\,700 + 1\,122\,800\,X_0 + 1\,040\,590\,X_1 + 958\,400\,X_2 + 876\,140\,X_3 + 793\,920\,X_4 + 719\,110\,X_5 + 644\,030\,X_6 + 569\,090\,X_7 + 494\,280\,X_8 + 419\,330\,X_9 + 344\,460\,X_{10} + 269\,580\,X_{11} + 202\,190\,X_{12} + 134\,790\,X_{13})\,L$$

and similar expressions when the differentiation is made with reference to the other independent variables, $X_2 \ . \ . \ . \ X_{13}$.

These values are not copied out in full, as the work is very voluminous. Similarly, the method is only indicated in the case of Arch 15.

Arch 15.—For this the general expression for H is:

$$H = 6\,802 \int_0^L (P_{15} + X_{15}) \frac{\delta\,(P_{15} + X_{15})}{\delta X} d\,l$$

$$= 6\,802 \int_0^L (796.87 + X_{15}) \frac{\delta\,(796.87 + X_{15})}{\delta X} d\,l.$$

If we substitute for X_{15} the value from Equation (18), we have

$$H = 6\,802 \int_0^L (796.87 + 15.66\,X_0 + 14.44\,X_1 + 13.22\,X_2 + 12\,X_3 + 10.78\,X_4 + 9.67\,X_5 + 8.56\,X_6 + 7.44\,X_7 + 6.33\,X_8 + 5.22\,X_9 + 4.11\,X_{10} + 3\,X_{11} + 2\,X_{12} + X_{13}) \times \frac{\delta\,(796.87 + 15.66\,X_0 \ . \ . \ . \ X_{13})}{\delta X} d\,l$$

which, for the different independent variables, becomes:

X_0 as variable:

$$H = 6\,802\ (15.66)\ (796.87 + 15.66\ X_0 \ldots X_{13})\ L = (84\,918\,190 + 1\,669\,518\ X_0 + 1\,539\,272\ X_1 + 1\,409\,026\ X_2 + 1\,278\,780\ X_3 + 1\,148\,534\ X_4 + 1\,030\,128\ X_5 + 911\,723\ X_6 + 793\,317\ X_7 + 674\,912\ X_8 + 556\,506\ X_9 + 438\,101\ X_{10} + 319\,695\ X_{11} + 213\,130\ X_{12} + 106\,565\ X_{13})\ L$$

and similar expressions when the differentiation is made with reference to the other independent variables, $X_1 \ldots X_{13}$.

Vertical Girder.

The second term of Equations (15) gives that part of the final equations due to the work in the vertical girder. If this term, for convenience, is called V, its value for the several panels and variables will be the following:

Panel 1.—X_0 as variable:

$$V = 0.0871\ L^2\ X_0$$

and the values for the other variables vanish.

Panel 2.—X_0 as variable:

$$V = + 0.6097\ L^2\ X_0 + 0.2175\ L^2\ X_1$$

X_1 as variable:

$$V = 0.2175\ L^2\ X_0 + 0.0871\ L^2\ X_1$$

the values for the other variables being equal to 0.

Panels 3-15.—The corresponding expressions for the remaining panels of the vertical girder will be of the same general form as those deduced for the first two panels.

In obtaining the value of V for the bottom panel (15) the variable, X, was, of course, expressed in terms of $X_0 \ldots X_{13}$.

Method of Obtaining Final Equations.

The final equations are obtained from the values for H and for V above by adding all the terms which correspond to the same independent variable, $X_0, X_1 \ldots X_{13}$, and equating them to zero.

In the case of no contact at the sill, the values of H for the bottom girder (15) must be included, as this girder then carries the full load which comes on it.

For perfect contact, the bottom girder does no work as an arch, and hence the H's for this girder must be omitted.

If the contact is such that the bottom girder does some work in arch action, a portion of its H's may be counted. In other respects, the method of calculation is independent of the degree of sill contact.

It should be noted that L (the length of the leaf, 787 in.) enters all values of H in the first power and those of V in the second. By dividing the final equations by L, it will be eliminated from the H terms, but will remain in the first power in those corresponding to V.

From their method of derivation, the resulting final equations should be symmetrical as to coefficients, and, in the equations for the solution of the problem, an average has been used where two coefficients which should be identical have differed by a slight amount. There have been no large discrepancies, proving to a considerable extent the accuracy of the work.

Only five significant figures were retained.

Final Equations of Conditions.—The final equations, as thus obtained, are the following:

(Case A).—No Contact at Sill.

X_0 as variable:

$$3\,007\,500\ X_0 + 2\,762\,700\ X_1 + 2\,530\,200\ X_2 + 2\,298\,200\ X_3 + 2\,066\,800\ X_4 + 1\,856\,900\ X_5 + 1\,647\,600\ X_6 + 1\,439\,300\ X_7 + 1\,232\,100\ X_8 + 1\,025\,700\ X_9 + 820\,580\ X_{10} + 616\,660\ X_{11} + 434\,260\ X_{12} + 252\,900\ X_{13} - 30\,032\,300 = 0.$$

X_1 as variable:

$$2\,762\,700\ X_0 + 2\,561\,000\ X_1 + 2\,335\,100\ X_2 + 2\,121\,400\ X_3 + 1\,908\,200\ X_4 + 1\,714\,800\ X_5 + 1\,521\,700\ X_6 + 1\,329\,500\ X_7 + 1\,138\,200\ X_8 + 947\,700\ X_9 + 758\,250\ X_{10} + 569\,920\ X_{11} + 401\,420\ X_{12} + 233\,890\ X_{13} - 26\,344\,200 = 0.$$

X_2 as variable:

The method used for solving these equations is given in the Appendix. The values obtained were the following:

$X_0 = +154.60$	$X_5 = -94.82$	$X_{10} = +90.18$
$X_1 = +69.59$	$X_6 = +21.62$	$X_{11} = +33.31$
$X_2 = -26.30$	$X_7 = -82.31$	$X_{12} = -11.51$
$X_3 = -127.50$	$X_8 = +37.81$	$X_{13} = +70.62$
$X_4 = -36.99$	$X_9 = -84.21$	

and, from Equations (21) and (22),

$$X_{14} = -135.1$$
$$X_{15} = +121.0$$

These values are in pounds per linear inch of horizontal arch. In Fig. 3 (*B*), of Plate XVII, they are given per linear foot. Here, as in all other cases when X is positive, the vertical girder presses against the horizontals in a down-stream direction.

X_{13} as variable:

$$146\,300\,X_0 + 135\,600\,X_1 + 124\,900\,X_2 + 114\,200\,X_3 + 103\,500\,X_4 + 93\,720\,X_5 + 83\,930\,X_6 + 74\,150\,X_7 + 64\,400\,X_8 + 54\,620\,X_9 + 44\,850\,X_{10} + 35\,090\,X_{11} + 26\,300\,X_{12} + 21\,870\,X_{13} - 7\,014\,000 = 0.$$

The values of the variables in these equations are:

$X_0 = +156.10$	$X_5 = -22.82$	$X_{10} = +37.12$
$X_1 = +81.23$	$X_6 = +124.1$	$X_{11} = -198.5$
$X_2 = +0.2828$	$X_7 = +14.93$	$X_{12} = -460.7$
$X_3 = -87.82$	$X_8 = +135.9$	$X_{13} = -837.5$
$X_4 = +27.67$	$X_9 = -38.78$	

and, substituting in Equations (21) and (22),

$$X_{14} = -1\,208.0$$
$$X_{15} = +2\,276.0$$

all these values being pounds per linear inch. In Fig. 3 (*A*), of Plate XVII, these values are given in pounds per linear foot.

49½-Foot Gate.—This gate consists of the nine panels of the 77½-ft. gate which are nearest the top, but the bottom girder, (9), is somewhat modified, so that $F_9 = 120$ sq. in.; $I_9 = 140\,000$ in.^{4}; $e_9 = 21$ in.; and $P_9 = 622.8$ lb. per lin. in.

The static equations for equilibrium give:

$$X_8 = -(9.4\,X_0 + 8.3\,X_1 + 7.2\,X_2 + 6.1\,X_3 + 5\,X_4 + 4\,X_5 + 3\,X_6 + 2\,X_7)$$
$$X_9 = +(5.4\,X_0 + 7.3\,X_1 + 6.2\,X_2 + 5.1\,X_3 + 4\,X_4 + 3\,X_5 + 2\,X_6 + X_7)$$

The equations of conditions become:

(*Case A*).—*No Contact at Sill.*

$$388\,880\ X_0 + 342\,380\ X_1 + 307\,990\ X_2 + 249\,430\ X_3 + 203\,190\ X_4 + 161\,460\ X_5 + 120\,180\ X_6 + 79\,476\ X_7 - 41\,019\,000 = 0.$$

$$327\,170\ X_0 + 288\,310\ X_1 + 249\,430\ X_2 + 222\,680\ X_3 + 171\,730\ X_4 + 136\,590\ X_5 + 101\,740\ X_6 + 67\,314\ X_7 - 32\,131\,000 = 0\ .$$

$$266\,080\ X_0 + 234\,630\ X_1 + 203\,190\ X_2 + 171\,730\ X_3 + 149\,180\ X_4 + 111\,720\ X_5 + 83\,305\ X_6 + 55\,154\ X_7 - 25\,820\,000 = 0.$$

$$211\,180\ X_0 + 186\,320\ X_1 + 161\,460\ X_2 + 136\,590\ X_3 + 111\,720\ X_4 + 98\,020\ X_5 + 66\,544\ X_6 + 44\,099\ X_7 - 18\,558\,000 = 0.$$

$$157\,050\ X_0 + 138\,620\ X_1 + 120\,180\ X_2 + 101\,740\ X_3 + 83\,305\ X_4 + 66\,544\ X_5 + 56\,585\ X_6 + 33\,044\ X_7 - 12\,931\,000 = 0.$$

$$103\,790\ X_0 + 91\,640\ X_1 + 79\,476\ X_2 + 67\,314\ X_3 + 55\,154\ X_4 + 44\,099\ X_5 + 33\,044\ X_6 + 28\,791\ X_7 - 5\,697\,700 = 0.$$

The values of the variables become:

$X_0 = +310.1$	$X_3 = -96.30$	$X_6 = -301.4$	$X_9 = +1\,615.6$
$X_1 = +184.4$	$X_4 = -74.07$	$X_7 = -593.4$	
$X_2 = +52.4$	$X_5 = -225.5$	$X_8 = -871.9$	

Discussion of Results.

The values of the variables, X_0, X_1, etc., previously obtained, give the reactions between the horizontal and vertical girders for the two gates and different conditions of sill contact, and $(P_0 + X_0)$, $(P_1 + X_1)$, etc., are the resultant girder loads per linear unit of leaf. Plate XVII gives these results in graphic form for the 77 ft. 6-in. and 49 ft. 6-in. gates, respectively.

On this plate, Figs. 1 and 6 show cross-sections of the leaf with its dimensions, moments of inertia, etc., also the total water pressure acting against the gate, and Figs. 3 and 8 give the reactions between the horizontals and the vertical girder, in pounds per linear foot of gate leaf, *B* being for no contact and *A* for perfect contact at sill.

Figs. 2 and 7 of Plate XVII give the resultant loads per linear foot on the different horizontals for the three different cases: *A*, vertical

stiffness and perfect sill contact; *B*, vertical stiffness but no sill contact; and *C*, no vertical stiffness at all.

Figs. 4 and 9 of Plate XVII show the deflections of the miter posts, that is, the distance they move down stream parallel with the axis of the lock for the three cases just mentioned. These last curves are in general agreement with those showing the resultant girder loads.

Loads on Horizontals.—The curves show that, with no contact at the sill, the values of *X* (reactions of vertical against horizontal girders) are quite small, so that, except at the very top, the deviations from a purely hydrostatic loading are inconsiderable and due to accidental causes. With "perfect" contact, the girders in the lower portion of the leaf (from one-third to one-half the height) were relieved of a large part of their hydrostatic load, the horizontals higher up receiving a proportionately greater loading. The girders closest to the top showed, in all cases, the largest proportional increase. In the 77 ft. 6-in. gate, there was also an increase for the horizontals in the middle third of the height. As a whole, however, the effect of the vertical stiffness was decidedly greater for the 49 ft. 6-in. gate.

In proportioning the Panama gates, it was decided to use a load corresponding to a head of 20 ft. for all girders within 20 ft. of the top. For those lower down, the hydrostatic head was taken, but, in gates more than 75 ft. high, the girders in the middle third of the height had this load increased by from 5 to 10 per cent.

For smaller gates, the effect of vertical stiffness would probably be greater than for the very high and rather thin Panama gates.

There is no reason, however, to doubt that the common assumption of hydrostatic loading, except for a few girders near the top, will give safe results. In the lower part of the leaf, the stresses in actual service will generally be quite small in a gate designed for the hydrostatic head, as it is very probable that there will be some contact at the sill. However, the increase in cost involved is not great, and in any event the miter gate will weigh much less than any form of caisson or single-leaf gate.

Reaction of Gate Against Sill.—For the case of no contact, the reaction, of course, is equal to zero. For "perfect contact", the sill pressure is equal to the end reaction, *X*, at the bottom of the vertical girder plus the direct water load, *P*, on the lowest arch.

These values for the two gates are as follows: (See Figs. 2 and 7 of Plate XVII).

For the 77 ft. 6-in. gate,

$$12\,(P_{15} + X_{15}) = 9\,560 + 27\,322 = 36\,882 \text{ lb. per lin. ft.}$$

or, $$\frac{36\,882}{184\,875} = 19.4\% \text{ of the total load of the gate.}$$

For the 49 ft. 6-in. gate,

$$12\,(P_9 + X_9) = 7\,474 + 19\,387 = 26\,857 \text{ lb. per lin. ft.}$$

or, $$\frac{26\,857}{76\,565} = 35.1\% \text{ of the total load.}$$

It will be noted that the total sill reaction is proportionately greater for the lower gate.

In case there is some elastic movement of the sill under pressure, the sill reaction and also the loads on horizontals and the deflections will be values intermediate between Cases *A* and *B*.

As stated previously, it is believed that Case *A* is a sufficient maximum.

For small locks, it is not unusual to make the masonry sill strong enough to withstand the theoretical maximum of $66\frac{2}{3}\%$ of the total water pressure acting against the gate. For the large proportions at Panama, it would have been difficult to make the sill walls strong enough to carry this maximum, and it seemed entirely unnecessary. It was deemed quite safe to assume a pressure of 50 000 lb. per lin. ft. of sill or about one-quarter of the whole load on the gate.

Stresses in the Vertical Bracing.—This bracing corresponds to the vertical girder in the computations, the loads acting on it being the forces, X_0, X_1, etc., applied transversely at distances corresponding to the spacing of the horizontal girders.

The chord stresses are readily obtained from the values shown on Plate XVII. The unit stresses were found to be not more than 4 500 lb. per sq. in. in any part of the bracing.

The shears for proportioning the web thickness and the rivet connections were obtained in a similar manner from the transverse forces, X_0, X_1, etc.

APPENDIX

Method for the Solution of Simultaneous Equations.

For the solution of simultaneous equations of the first degree, the method originated by the celebrated astronomer, Gauss, is probably the best for practical use in the engineer's office. The solution by determinants is theoretically attractive, but its application is not satisfactory. Graphical methods are the best in some cases, but can hardly be used where the coefficients of the different variables differ widely in magnitude, and where a high degree of accuracy is required.

Gauss' method in a simple form may be stated as follows:

Given, say, three simultaneous equations of the form:

$$a\,x + b\,y + c\,z + m = 0 \quad \ldots\ldots(1)$$
$$b\,x + d\,y + e\,z + n = 0 \quad \ldots\ldots(2)$$
$$c\,x + e\,y + f\,z + p = 0 \quad \ldots\ldots(3)$$

to find the values of x, y, and z.

From Equation (1), we obtain:

$$x = -\frac{b\,y + c\,z + m}{a}$$

and substituting in Equations (2) and (3), we have:

$$\left(d - \frac{b}{a}\,b\right) y + \left(e - \frac{b}{a}\,c\right) z + \left(n - \frac{b}{a}\,m\right) = 0 \ldots\ldots(2^1)$$

$$\left(e - \frac{c}{a}\,b\right) y + \left(f - \frac{c}{a}\,c\right) z + \left(p - \frac{c}{a}\,m\right) = 0 \ldots\ldots(3^1)$$

which may be written,

$$d_1\,y + e_1\,z + n_1 = 0 \ (2^1)$$
$$e_1\,y + f_1\,z + p_1 = 0 \ (3^1)$$

In these two equations the coefficients are the same as in Equations (2) and (3), with a subscript added.

From Equations (2^1) and (3^1), we have, in the same way,

$$\left(f_1 - \frac{e_1}{d_1}\,e_1\right) z + \left(p_1 - \frac{e_1}{d_1}\,n_1\right) = 0 \quad \ldots\ldots(3^2)$$

which may be written,

$$f_2\,z + p_2 = 0 \quad \ldots\ldots(3^2)$$

From Equation (3^2), we obtain the value of $z = -\frac{p_2}{f_2}$, and the value of x and y by substituting in the first and second sets of equations.

By writing the equation in tabular form, the relation of the successive coefficients is made clearer, and a valuable check on the arithmetical work is obtained at each step.

TABLE 1.

——	x	y	z	——	——
Equation (1).....	a	b	c	m	$q = a + b + c + m$
Equation (2).....	b	d	e	n	$r = b + d + e + n$
Equation (3).....	c	e	f	p	$s = c + e + f + p$

TABLE 2.

——	y	z	——	——
Equation (2^1).....	d_1	e_1	n_1	r_1
Equation (3^1).....	e_1	f_1	p_1	s_1

TABLE 3.

——	z	——	——
Equation (3^2).....	f_2	p_2	s_2

On examining Equations (2^1) and (3^1), it will be seen that the coefficients, d_1, e_1, etc., are always of the form,

$$T - \frac{U\,V}{H},$$

in which,

T = the corresponding coefficient in Equations (2) and (3), that is, the coefficient of the same variable, omitting the subscript;

U = the coefficient in the top horizontal line, that is, in Equation (1) vertically above T;

V = the last coefficient to the left in the same horizontal line with T; and

H = the coefficient of x in the top row.

The values of q, r, and s, in the last column of Table 1 are written down by simply adding the preceding coefficients in each horizontal row.

In Tables 2 and 3, r_1, s_1, s, like the coefficients, d_1, e_1, n_1, etc., are obtained by the formula, $T - \frac{U\,V}{H}$, previously given.

The check consists in adding up each horizontal line; the last term should be equal to the sum of the preceding ones, that is, for instance, s should equal $e_1 + f_1 + p_1$.

Numerical Example.

$$482.5\,x + 348.4\,y + 238.6\,z + 140.7\,u - 48\,915 = 0$$
$$348.4\,x + 280.5\,y + 186.0\,z + 111.4\,u - 37\,167 = 0$$
$$238.6\,x + 186.0\,y + 146.9\,z + 82.0\,u - 24\,484 = 0$$
$$140.7\,x + 111.4\,y + 82.0\,z + 66.0\,u - 11\,760 = 0$$

TABLE 4.

x	y	z	u	——	——
482.5	348.4	238.6	140.7	− 48 915	− 47 704.8
348.4	280.5	186.0	111.4	− 37 167	− 36 240.1
238.6	186.0	146.9	82.0	− 24 484	− 23 330.5
140.7	111.4	82.0	66.0	− 11 760	− 11 359.9

TABLE 5.

y	z	u	——	——
28.92	13.70	9.80	− 1 847	− 1 794.5
13.70	28.90	12.42	− 296	− 2 410.0
9.80	12.42	24.97	+ 2 503	+ 2 550.1

TABLE 6.

z	u	——	——
22.41	7.78	+ 579	+ 609.2
7.78	21.65	+ 3 128.9	+ 3 158.3

TABLE 7.

	u	——	——
	18.95	+ 2 927.9	+ 2 946.84

The coefficients for the first equation in Table 5, will be,

$$280.5 - \frac{348.4 \times 348.4}{482.5} = 28.92$$

$$186.0 - \frac{238.6 \times 348.4}{482.5} = 13.70$$

$$111.4 - \frac{140.7 \times 348.4}{482.5} = 9.80$$

$$-37\,167 - \frac{48\,915 \times 348.4}{482.5} = -1\,847$$

and, as a check, the last term

$$\left(-36\,240.1-\frac{47\,704.8\times 348.4}{482.5}\right)=-1\,794.5$$

which should and does equal the sum of the preceding terms.

The roots are $x=+58$, $y=+103$, $z=+27$, and $u=-154$.

The computations were carried out mainly with the use of the well-known cylindrical slide-rule of Edwin Thacher, M. Am. Soc. C. E., and the "Millionaire" multiplying machine.

Although such operations are necessarily somewhat tedious, the set of equations containing fourteen variables was solved by two computers in less than 15 hours of actual work.

MEMOIRS OF DECEASED MEMBERS

MENDES COHEN, Past-President, Am. Soc. C. E.*

DIED AUGUST 13TH, 1915.

Mendes Cohen was born in Baltimore, Md., on May 4th, 1831. His family, previously prominent in Europe, came to America before the Revolution, its first representative going to Lancaster, Pa., in 1773, afterward serving in the war and, later, living in Richmond, Va. Mr. Cohen's grandfather went to Baltimore in 1808. Two of the family served in the War of 1812. The father of Mendes Cohen, a banker in Baltimore, died in 1847, and the son, who had been under the instruction of a private tutor, directly entered the works of Ross Winans, the builder of early American locomotives. In 1851, he was made an Assistant Engineer on the Baltimore and Ohio Railroad, and served on the construction of the Broad Tree Tunnel; then, having been transferred to the Motive Power Department, he was engaged in the adaptation of wood-burning passenger locomotives to coal burning. He also worked out the method adopted for handling the traffic on the 10% temporary grade over the Kingwood Tunnel, a remarkable achievement in railroad operation.

In 1855, when only twenty-four years old, Mr. Cohen had already become known as an especially capable railroad official, and was made Assistant Superintendent of the Hudson River Railroad. He was with that Company until 1861, when he succeeded Gen. George B. McClellan as operating head of the Ohio and Mississippi Railroad, first as Superintendent and, later, as President and Superintendent. Soon after the close of the Civil War, he was engaged, for a short time, on special work for the Philadelphia and Reading Railway.

From 1868 to 1871 Mr. Cohen was Comptroller and Assistant to the President of the Lehigh Coal and Navigation Company. In 1872, he became President of the Pittsburgh and Connellsville Railroad, which was subsequently consolidated with the Baltimore and Ohio System. He retired in 1875 from official positions in connection with companies, but continued his practice in Baltimore as a Consulting Engineer.

Mr. Cohen is survived by his widow, Mrs. Jessie (Nathan) Cohen.

Mr. Cohen was a member of the Board appointed by the President, in 1894, to report on a route for the Chesapeake and Delaware Ship Canal. From 1893 to 1904, he was Chairman of the Baltimore Sewer-

* Memoir prepared by the following Committee: John Bogart and J. E. Greiner, Members, Am. Soc. C. E.

age Commission. He was for twenty-one years the Secretary of the Maryland Historical Society, serving for nine years as its President. He was also Vice-President of the American Jewish Historical Society from 1897 until his death. His acquaintance with history, especially that of Maryland, was remarkable. He was a member of the Municipal Art Commission of Baltimore from 1892 until his death. For many years he was also an active member of the Board of Trustees of the Peabody Institute.

During many years Mr. Cohen was a strong and influential citizen in the city of his birth and long residence. He was consulted in all matters of great importance, and his judgment, always given after deliberate consideration, had great weight. He was a serious, religious man; socially of the best in Baltimore, in fact, a worthy representative of one of the old strong families of the United States.

Mr. Cohen was a man of strong character, with broad experience, not only in technical and engineering matters, but also in well-informed studies of affairs and conditions of business and social life. He was a man of much reserve, wise in conference, ready to consider and give weight to the suggestions of others, and did not hesitate to express his own judgment and opinion with clear statements of reasons for them. He was, therefore, a strong and valuable associate and adviser in the direction of business matters. This was particularly evident in the consideration of the problems arising in the affairs of a growing institution, such as the Society was during the years of his close connection with its management. He never lost interest in its welfare, nor forgot the responsibilities of a Past-President. He highly appreciated the honor of his election as its President.

Mr. Cohen became a Member of the American Society of Civil Engineers on December 4th, 1867. The Society, founded in 1852, had been inactive during the Civil War, but was kept alive by a small group of members, the officers elected in 1852 continuing their nominal functions. In 1867, the Society was resuscitated, James P. Kirkwood, one of the original members, becoming President in succession to James Laurie, who had held the office from 1852 to 1867. Mr. Cohen was elected to membership in that year, and, at the time of his death, had only one living associate of those who became members in 1867. The Society had only twenty-six members at the time of his election.

Although then only thirty-six years old, Mr. Cohen had already held responsible positions in railroad operation and management and his well-informed judgment was at once of value in the building up and judicious expansion of the activities of the Society. He served as a Director in 1888, as Vice-President in 1890, and as President in 1892.

ELMER LAWRENCE CORTHELL, President, Am. Soc. C. E.*

DIED MAY 16TH, 1916.

Elmer Lawrence Corthell was born in South Abington (now Whitman), Mass., in 1840, the son of James Lawrence and Mary Gurney Corthell. He was educated at the South Abington High School and Phillips Exeter Academy. He entered Brown University in 1859, studying until the outbreak of the Civil War in 1861. At the first call for volunteers, he enlisted in the First Rhode Island Artillery, Battery D, and served in stations from private to the rank of Commander of field artillery, until his return with rank of Captain at the end of the war. As a soldier, he saw service principally in Virginia and North Carolina.

At the close of the war Mr. Corthell returned and resumed his studies at Brown University from which he was graduated in 1867 with the degree of Master of Arts, and Phi Beta Kappa honors.

In 1894 he received from his Alma Mater the honorary degree of Doctor of Science. From boyhood it had been Mr. Corthell's aim and ambition to study for the ministry in the Baptist Church, but on completing his university course, on account of his health, and the advice of his physician to select a more active profession, he chose Civil Engineering and entered the employ of the late Samuel Barrett Cushing, M. Am. Soc. C. E., a prominent engineer in Providence, R. I., where he practiced and did field work in railroad, mill, dam, bridge, city, and other construction.

In 1868 Mr. Corthell was appointed Assistant Engineer on the construction of the Hannibal and Naples Railroad in Illinois, now a part of the Wabash System. In 1869, he was Engineer on the location and construction of the Hannibal and Missouri Railroad. In 1870-71, he was Chief Assistant Engineer, under the late Col. E. D. Mason, M. Am. Soc. C. E., in the construction of the railroad bridge over the Mississippi River at Hannibal, Mo. From 1871 to 1875, he was Chief Engineer of the Sny Island Levee, 51 miles in length, on the east bank of the Mississippi River. While engaged in that work he was, in 1873-75, Chief Engineer on the construction of the bridge over the Mississippi River, at Louisiana, Mo., for the Chicago and Alton Railroad. The draw-span of this bridge was 444 ft. long—at that time, the longest in the world.

In July, 1875, Mr. Corthell went to the mouth of the Mississippi River, and from that time until 1880 was Assistant to the late Capt. James B. Eads, M. Am. Soc. C. E., in the construction of the jetties

* Memoir prepared by the following committee: John F. Wallace and J. A. Ockerson, Past-Presidents, Am. Soc. C. E., and W. J. Karner, Assoc. Am. Soc. C. E.

C. L. Borthell

at the South Pass mouth of the river. On account of ill-health, he came north early in 1880, and while convalescing, wrote his "History of the Jetties at the Mouth of the Mississippi River".*

From 1881 to 1884, Mr. Corthell served as Engineer of the New York, West Shore and Buffalo Railroad Company, in charge of the construction of that road and the extension of the New York, Ontario and Western Railroad to connect with the West Shore. For about two years, during the construction of the West Shore Railroad, he was assisting Capt. Eads and Col. James Andrews in their plans for the construction of a ship railway across the Isthmus of Tehuantepec, Mexico, and, after he resigned his position with the West Shore Railroad Company, from 1884-87, he assisted Capt. Eads in promoting the Tehuantepec Ship Railway, taking charge, on the Isthmus, of the survey of the route for the railway, and exploiting it by visiting various cities in the United States, showing perfect working models of the railroad and a ship being placed in its cradle on the rails.

From March, 1887, until 1889, Mr. Corthell was associated in an engineering partnership, in New York City and Chicago, Ill., with the late George S. Morison, Past-President, Am. Soc. C. E., engaged in the construction of railroads, bridges, harbors, and water-works. During this partnership there were constructed, the Cairo Bridge over the Ohio River for the Illinois Central Railroad, then the longest steel bridge in the world, bridges over the Missouri River at Nebraska City and Sioux City, two bridges in Oregon, one at Jacksonville, Fla., and water-works at Bismarck, N. Dak.

From 1889 to 1890, he was Engineer of the St. Louis Merchants Bridge over the Mississippi River, having charge of the design and construction of the substructure and foundations.

During the same period, from 1889 to 1890, he was also Chief Engineer of the improvements at the mouth of the Brazos River, in Texas.

In 1889 and 1890 he was employed as a special Consulting Engineer in charge of terminal work in the City of Chicago for the Chicago, Madison and Northern Railroad, a subsidiary corporation of the Illinois Central Railroad,—the Chicago, Madison and Northern Railroad affording an entrance to Chicago from the West for the Illinois Central lines; and also in connection therewith for certain main and side-track facilities for the Atchison, Topeka and Santa Fe and the Chicago and Alton Railroads.

In 1889, Mr. Corthell made examinations, plans, and report on the proposed improvement of the harbor at Tampico, Mexico, for the Mexican Central Railroad and, later, had charge of the construction of the jetties as Chief Engineer.

During 1889 he was also President and Chief Engineer of the Southern Bridge and Railway Company, incorporated that year to build a

* Published in 1880 by John Wiley and Sons.

bridge over the Mississippi River, at New Orleans, and completed the plans and specifications for its construction.

In the following year (1890), he made a personal examination between the Great Lakes and Quebec, Canada, of the question of an enlarged waterway between Chicago, Duluth, and other ports of the Great Lakes and the Atlantic Seaboard, and wrote a paper on this subject for the Canadian Society of Civil Engineers* and the Western Society of Engineers at Chicago.

In 1891 Mr. Corthell visited Europe, with several important objects in view. As a Trustee of the University of Chicago, he examined six of the leading universities and technical schools of Europe in order to obtain information for the University in carrying out its purpose of establishing, in connection with it, a great School of Engineering and Architecture. As a member of a Committee of the Western Society of Engineers, engaged in solving the difficult railroad problem of Chicago, he examined in Europe thirty-five railroad terminals and complicated situations. He also examined twenty-six European harbors to secure special information for use in connection with his work at Tampico, Mexico, and elsewhere. He also examined nearly all the subways of the Old World, from Glasgow to Budapest.

In 1897, Dr. Corthell again visited Europe to examine a great variety of engineering works. Many of the results of his various examinations and investigations were published in the *Engineering Magazine*, in New York and London. The most extensive work done by him, however, during his two years in Europe, was on the subject of Maritime Commerce, its past, present, and future. In August, 1898, he presented the results of his work to the American Association for the Advancement of Science, which held its Fiftieth Anniversary, at Boston, Mass. The object of the paper was to show the development of commerce in the half century to come. On his return to the United States he was engaged as expert on several important works in the United States and Mexico.

Dr. Corthell sailed for Buenos Aires, Argentine Republic, in March, 1900, where, for more than two years, he was engaged in solving problems for commerce and reporting to the Minister of Public Works. Thirty-six different subjects were referred to him for investigation and report.

During the winter of 1902 and the spring of 1903, he delivered thirty-six lectures in thirty cities of the United States and Mexico, on "Two Years in Argentine as Consulting Engineer of National Public Works". These were delivered before universities and commercial bodies, also engineering societies, etc., at the request of the Argentine Government.

* *Transactions*, The Canadian Society of Civil Engineers, Vol V, p. 32 (1891).

At one time, Dr. Corthell made an examination, reports, and estimates for the Boston, Cape Cod, and New York Ship Canal.

The Governor of the State of New York, in 1894, appointed Dr. Corthell upon the Advisory Board of Consulting Engineers on the State Barge Canal, a position from which he resigned on account of his Brazilian work.

During 1904 and 1905 he was engaged on extensive commercial works in Brazil, at Para, in St. Catherina, and Rio Grande do Sul.

He represented the United States on the Permanent Commission of the International Congress of Navigation and was an active and influential member of that organization.

Mr. Corthell was married, in 1870, to Emily Theodate Davis, of Providence, R. I., who died in 1884, leaving two children, Mrs. E. S. Dewey, of Gloversville, N. Y., and Howard Lawrence Corthell, a Civil Engineer, of New York City. In 1900, he was married to Marie Kuchler, of Berne, Switzerland, who survives him. He also leaves one brother, Roland, of Boston, and one sister, Mrs. Annie C. Phipps, of Wollaston, Mass.

The various International Engineering Congresses always found Dr. Corthell an active participant, either in person or by important papers. At a meeting in Brussels, where all but six of the seventy-one papers were in other languages than English, he prepared for the Department of State, which had selected him as a delegate, a résumé of the entire proceedings, which formed a volume of 245 pages. The International Engineering Congress held during the Columbian Exposition was suggested by him, and its success was largely due to his work as Chairman of the Executive Committee having charge of that affair. When the recent Pan-American Scientific Congress, in Washington, D. C., was contemplated, the Department of State again called upon Dr. Corthell to aid in the organization of the meeting, and he rendered valuable assistance in making this affair a success.

After years of exceedingly active work, Dr. Corthell found his chief satisfaction in the fact that his works had been beneficial to commerce by sea, river, canal, and rail, and he could point with pride to the results as having aided in reducing the cost of transportation on land and water, to the benefit of mankind.

A prolific writer on engineering subjects, his printed papers fill many volumes. Another of his activities concerned the establishment of a civilian reserve corps of engineers, and he was one of the leaders, if not the leader, in this project. After his election to the Presidency of the American Society of Civil Engineers, Dr. Corthell had taken an active part in the proposal to have the Society join the three other National Engineering Organizations in the United Engineering Societies Building in New York.

Dr. Corthell was a member of the following societies: American Institute of Consulting Engineers, Inc., of which he served as President in 1915-16; The Canadian Society of Civil Engineers; The Institution of Civil Engineers of Great Britain; The Society of Arts of Great Britain; Member d'Honneur, and Corresponding Member of the French Society of Civil Engineers; The American Association of Civil Engineers and Architects; American Railway Engineering Association; The Boston Society of Civil Engineers; The Western Society of Civil Engineers, Chicago, Ill., of which he was President in 1889; Honorary Member of the Geographical and Statistical Society of Mexico; American Geographical Society; The National Geographical Society, Washington, D. C.; Fellow, Royal Geographical Society, London, England; Fellow, American Association for the Advancement of Science; Honorary Member, Engineering Society of Portugal, The Institution of Engineers of the River Plate, The Centre de Navigacion Transatlantica, and Sociedad Cientifica of Argentine; Franklin Institute, Philadelphia, Pa.; American Highway Association; Pan-American Society; Founder, Pan-American Chamber of Commerce; Member, Chamber of Commerce of the United States; and Member, Board of Consulting Engineers, Barge Canals, New York State.

Dr. Corthell was also a member of the following military and patriotic associations: Grand Army of the Republic; Military Order of the Loyal Legion; Sons of the American Revolution; New England Society; and Society of the Army of the Potomac.

He was also a member of several academical and university societies and clubs, including the University Club, New York City, Phi Beta Kappa and Sigma Chi Societies, and of the Engineers Club of Rio de Janeiro.

After a half century of continuous work devoted to the service of his fellow-man and the advancement and up-building of the Engineering Profession, he has now passed away, leaving the Profession and the world better and enriched by his work, which has been a shining example of an enthusiastic, industrious, useful life.

Throughout it all, in adversity as well as in prosperity, he met his daily problems with enthusiasm, and ever had his hand extended to encourage and help all with whom he came in contact, particularly the younger members of the Profession. He was always ready to assist them, not only by advice and counsel, but by financial aid and the use of his influence, in obtaining positions and advancements.

His memory will always flourish in the hearts of those who have been favored by his acquaintance.

Dr. Corthell was elected a Member of the American Society of Civil Engineers, on September 2d, 1874. He served two terms as Vice-President, in 1889 and 1893-94, and was elected President on January 19th, 1916.

CHARLES CONRAD SCHNEIDER, Past-President, Am. Soc. C. E.*

DIED JANUARY 8TH, 1916.

Charles Conrad Schneider, the son of Julius and Emilie Schneider, was born in Apolda, Saxony, on April 24th, 1843. He attended school in his native city, and then served an apprenticeship in a machine shop. After this he attended the Royal School of Technology in Chemnitz, Saxony, from which he was graduated in 1864. He afterward devoted a few years to active professional practice as a Mechanical Engineer.

In 1867, Mr. Schneider came to the United States and, for three years, was employed as a Draftsman with the Rogers Locomotive Works, at Paterson, N. J.

He was quick to perceive the great field for development which lay in the branch of the profession which he subsequently adopted, and his name will be prominently associated for all time with those members of the profession who have done so much in the past 40 or 50 years to study, develop, and perfect the science and art of Structural Engineering.

His first work in this line was with the Michigan Bridge and Construction Company, of Detroit, Mich., with which Company he accepted a position as Assistant Engineer in 1871. In 1873, he took charge of the Engineer's Office of the Erie Railroad Company in New York City, under the late Octave Chanute, Past-President, Am. Soc. C. E., Chief Engineer. In this position, one of Mr. Schneider's duties was to check the strain sheets and plans submitted by bridge companies. Up to this time this had not been the general practice, the railroads depending mainly on the bridge companies for the correctness of the designs. He also organized a thoroughly trained inspection force. At this time experienced inspectors could hardly be obtained, and the work was generally accepted without inspection. Mr. Schneider selected a number of young men from the office and shops, who showed practical ability, and gave them instructions which enabled them to inspect the work in the shops, both as to quality and progress.

Bridge work up to this time had usually been let on a competitive lump-sum basis. Mr. Schneider soon found that this method was unsatisfactory, and the Railroad Company's officials decided to make their own plans; and it was Mr. Schneider's duty to prepare them. The bridge requirements for 1874 were designed in this way, and the work was let on a pound-price basis, and this, in all probability,

* Memoir prepared by the following Committee: Paul L. Wolfel, Richard Khuen, Jr., and O. E. Hovey, Members, Am. Soc. C. E.

was the first instance where bridge work was let by the pound, a procedure which Mr. Schneider always favored.

In 1876 and the early part of 1877, he was engaged by the Board of Engineers (sometimes called the Steinway Commission), appointed by the Long Island Bridge Company, to prepare and pass on plans for a railroad and highway bridge across the East River, to connect Long Island with New York City. It was the intention to locate this bridge between 76th and 77th Streets, this site having been selected as the narrowest point in the East River. The plan required a 734-ft. span across the west channel and a 618-ft. span across the east channel. The project, however, was not carried out at this time, on account of the financial condition of the Company.

From May, 1877, to July, 1878, Mr. Schneider was associated with the Delaware Bridge Company, of New York, as a Designer. Charles Macdonald, Past-President, Am. Soc. C. E., was President of this Company. During this period the Delaware Bridge Company made an arrangement with the Edge Moor Iron Company, of Wilmington, Del., to manufacture the ironwork of the bridges built by the former company, and Mr. Schneider was stationed at Edge Moor where he had charge of the design and construction of various bridges, including the Rockville Bridge over the Susquehanna River, near Harrisburg, Pa., on the Pennsylvania Railroad, the Cohoes Bridge, on the Delaware and Hudson Railroad, and several smaller ones.

On August 1st, 1878, he opened his own office in New York City, specializing in the design of bridge and structural work. One of the first pieces of work handled by him was a number of Howe truss spans for the Canadian Pacific Railway, the most important of which was for the Stony Creek Viaduct. This bridge carried traffic for the Canadian Pacific Railway until 1893, when it was replaced by a large arch span. Mr. Schneider's connection with the Canadian Pacific Railway Company dates from this time. For this Company he acted as Consulting Engineer, in numerous cases, almost to the end of his life.

One of the most important structures for this railroad was the 527-ft. cantilever bridge over the Fraser River, built by Mr. Schneider in 1887. This was one of the first cantilever bridges built in America, and it carried traffic until 1910, when it was taken down to make room for a structure of greater capacity; but it was re-erected across a chasm known as Niagara Ravine, on the line of the Esquimault and Nanaimo Railway (operated by the Canadian Pacific Railway), near Victoria, B. C. Both these structures were considerably ahead of their time, and have not been improved on by the most recent practice, except in a very few features.

In more recent years, Mr. Schneider passed on the design of the Lethbridge Viaduct, for the Canadian Pacific Railway, and also quite a number of smaller structures, including some Scherzer and Strauss bascule bridges. He was also called in consultation by this Railway Company for the reconstruction of the St. Lawrence River Bridge, near Montreal, Que., where the rebuilding of the superstructure and the remodeling of the piers for a wider and heavier bridge involved numerous difficult and interesting problems.

Numerous other structures were handled by Mr. Schneider in his New York office, the most important of which was the cantilever bridge over the Niagara River for the Grand Trunk Railroad. He wrote a highly interesting paper* about this structure for the Society, for which he was awarded the Rowland Prize in 1886.

He also designed all the interior steel framework and the anchorage for the Statue of Liberty in New York Harbor during this time.

When, in 1886, competitive designs were requested for a crossing over the Harlem River, by the Commission appointed by the City of New York, Mr. Schneider was awarded first prize for his plans. His friends have always regretted that his very beautiful and correctly conceived design had not been built in place of the structure which is now known as the Washington Bridge.

From 1879 to 1883, Mr. Schneider was associated with the late George S. Morison, Past-President, Am. Soc. C. E., on a number of important structures, such as the Plattsmouth, Bismarck, and Blair Bridges across the Missouri River, and the Snake River Bridge, at Ainsworth, Wash.

In 1886, Mr. Schneider was a member of a board of consulting engineers appointed by the New York District Railway Company. His associates on this board were: William P. Trowbridge, Charles C. Martin, Julius W. Adams, John T. Fanning, Alfred P. Boller, Gen. Quincy A. Gilmore, Henry Morton, and Charles F. Chandler. This Company proposed to build an underground railway under Broadway, with a junction at 14th Street, one line passing up Madison Avenue and the other continuing north under Broadway.

In May, 1886, Mr. Schneider entered into an agreement with the A. and P. Roberts Company, of Philadelphia, Pa., owners of the Pencoyd Iron Works, to establish a Bridge and Construction Department in connection with its works, and, subsequently, was appointed Chief Engineer. Under his direction this Bridge and Construction Department developed into the largest and most progressive establishment of its kind in the United States, and gained an international reputation.

---

* "The Cantilever Bridge at Niagara Falls", *Transactions*, Am. Soc. C. E., Vol. XIV, p. 499.

Some of the most important structures built by the Pencoyd Iron Works under his supervision are the Delaware River Bridge, for the Pennsylvania Railroad, near Philadelphia; the Niagara Falls and Clifton Arch Bridge, over the Niagara River, near the Falls; the Pennsylvania Railroad Company's old trainshed, in Jersey City; the Chesapeake and Ohio Bridge down the James River, in Richmond; and innumerable smaller structures in the United States, Mexico, and Japan.

In 1893, the Long Island Railroad Company took an interest in the project for a bridge over the East River at Blackwell's Island, previously referred to, with a view of establishing a terminal in New York City. Work was actually commenced, and, in 1894, competitive designs for the bridge were invited. The bridge was to accommodate four railroad tracks, with approaches and a terminal station west of Second Avenue, New York City. The plans adopted by the Long Island and New York Bridge Company were the designs made by Mr. Schneider, for the Pencoyd Iron Works, to which Company the contract for the entire steel superstructure of the bridge and approaches was awarded in March, 1895. Considerable work had been done on this bridge on piers and foundations, complete detailed drawings of the superstructure were made, and a portion of the material was rolled, when, on account of the death of Austin Corbin, President of the Long Island Railroad, the Company again became disorganized.

The American Bridge Company was formed in 1900, and, on May 21st, Mr. Schneider was elected Vice-President in charge of Engineering. He held this office until May 16th, 1901, when it was abolished and, on the same day, he was elected a Director and Vice-President of the American Bridge Company of New York, also in charge of Engineering. These offices he held until April 20th, 1903, when he became Consulting Engineer of the Company, which position he held during the remainder of his life. His associates in the American Bridge Company held him in the highest esteem, and felt that his influence for good in the Company was very potent, particularly in the early days of the organization. The first President of the Company expresses his estimate of him as follows:

"Mr. Schneider without question stood at the very head of his Profession and, in addition, I believe, never had an enemy in his entire career. I say this from intimate personal contact extending over a period of fifteen or twenty years. He had the confidence, not only of his fellow engineers, but of the consumer as well. His position at the head of the Engineering Department of the American Bridge Company gave to the organization a solid foundation among its competitors and the confidence of its customers. To the internal working of the Company, he was a great advantage at the start, as naturally many conflicting interests had to be considered, and I believe the entire staff was always willing to accept his decisions without friction."

During this time, Mr. Schneider continued his connection with the Canadian Pacific Railway as Consulting Engineer, and was also appointed Consulting Engineer for the Baltimore and Ohio Railroad Company.

In 1903, he was commissioned, in conjunction with Theodore Cooper, M. Am. Soc. C. E., by the Imperial Government Railways of Japan, to prepare a large set of standard plans for bridges for the Japanese Railways. These plans are still in use, and large tonnages have been shipped from the United States to Japan in conformity with them.

After the collapse of the Quebec Bridge, he was commissioned, by the Canadian Government, to make a report on the causes of the failure, which report he finished, in 1908, in the most thorough and exhaustive manner. In 1911, he was appointed by the Canadian Government as a member of the Board of Engineers for the rebuilding of the Quebec Bridge, which position he held until his death.

Mr. Schneider frequently contributed to technical papers. Besides his article on the cantilever bridge at Niagara Falls in 1886, previously mentioned, for which he received the Rowland Prize, in 1905 he received the Norman Medal from the Society for his paper on "The Structural Design of Buildings",* and, again, in 1908 the Norman Medal for his paper on "Movable Bridges."† These, together with his "Standard Specifications for Railway and Highway Bridges" and the volume of "Standard Details" which he compiled for the American Bridge Company, known to every structural engineer, form his chief contributions to technical literature.

When Mr. Schneider wrote his first railroad specifications for the Pencoyd Iron Works, he put his impact theory into practical use for the first time. This method of calculation has been adopted by the Government of India and by a large number of American railways, and has also been incorporated in the "Manual" of the American Railway Engineering Association and in its "General Specifications for Railway Bridges."

Mr. Schneider was a member of the American Railway Engineering Association, American Society for Testing Materials, the Verein Deutscher Ingenieure, in Germany, and the Engineers' Club of New York.

Mr. Schneider was dearly beloved by his many friends on account of his sterling character and his kindly disposition. He was always willing and ready to assist brother engineers with advice, giving to them freely from his rich fund of knowledge, and large indeed is the number of engineers to-day in responsible positions, who owe their training and their positions to him. He was most democratic in his ways and of a lovable disposition, and gained, in the highest degree,

* *Transactions*, Am. Soc. C. E., Vol. LIV, p. 371.

† *Transactions*, Am. Soc. C. E., Vol. LX, p. 258.

the respect of everybody who came in contact with him. He always stood for good work, good designs, and good details, and the Engineering Profession is greatly indebted to him for the present high standard that has been obtained in bridge and structural work. His was a most useful life, well lived, an example and an inspiration to the Profession, that will remain in the memory of all who had the privilege of knowing him.

He was married on January 8th, 1880, to Catherine Clyde, daughter of John J. and Ruth H. (Luther) Winters, of New York City. It was a great blow to him when he lost his only son in early boyhood. He is survived by his widow and his daughter, Helen, the wife of John Phillips Badenhausen, M. Am. Soc. C. E.

Mr. Schneider was elected a Member of the American Society of Civil Engineers on February 6th, 1884. He served as a Director in 1887 and from 1898 to 1900, and was elected Vice-President in 1902 and President in 1905. He was Chairman of the Library Committee in 1903 and Chairman of the Committee on Concrete and Reinforced Concrete from 1904 to 1911.

WILLIAM DOUGLAS PICKETT, Hon. M. Am. Soc. C. E.*

DIED MARCH 5TH, 1917.

William Douglas Pickett was the son of George Blackwell Pickett and Courtney (Heron) Pickett, members of prominent Virginia families. After their marriage, the Picketts had settled in the Tennessee River Valley, near Huntsville, Ala., where William Douglas Pickett was born on October 2d, 1827. After the death of his father, the family moved to Kentucky where the boy received his preliminary education, first in Richmond and then in Lexington. Having chosen Civil Engineering as his life work, he prepared himself for it at Transylvania University, from which he was graduated in 1845.

Immediately after his graduation, Mr. Pickett went to Texas, where he was engaged as Engineer in establishing the disputed lines of a large landed estate. While thus employed, war with Mexico was declared, and Mr. Pickett enlisted with the Texas Rangers. In 1848 when the war was ended, he returned to Kentucky and resumed the practice of his Profession. He was engaged on the reconstruction of the strap-railroad from Lexington to Frankfort, the first railroad built west of the Alleghany Mountains. He also served as Assistant Engineer on the railroad constructed from Lexington to Danville, and, later, as Chief Engineer, he located and built railroads in Tennessee, Georgia, Alabama, and Arkansas.

At the outbreak of the Civil War in 1861, Mr. Pickett was employed as Chief Engineer on the construction of the Memphis and Ohio Railroad in Tennessee. He resigned immediately and enlisted in the Confederate Army. He raised a company of civil engineers and received a commission as its Captain from the Governor of Tennessee. Shortly afterward, he was transferred to the staff of Major-General Pillow and designed and constructed a number of water batteries along the Mississippi River. While serving as Engineer Aide to General Leonidas Polk, Captain Pickett was requested by General Polk to accompany him to Columbus, Ky., to witness the test of a new gun. On the first discharge, the gun burst, killing a number of the men who served it, the concussion hurling both General Polk and Captain Pickett through the air. Although he escaped with his life, Captain Pickett's hearing was permanently impaired by the shock. He was afterward transferred to the staff of Major-General Hardee as Military Engineer, and took part in the battles of Shiloh, Perryville, Murfreesboro, and Missionary Ridge, as well as the engagements around Atlanta.

When General Hardee was transferred to a new Department, with headquarters at Charleston, S. C., Captain Pickett went with him,

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

and was actively engaged in the siege of Savannah, the evacuation of Charleston and Fort Sumter, and the march of Hardee's Army to a junction with that of General Johnston, and, on the surrender of the latter, in April, 1865, Captain Pickett was paroled as Colonel and Inspector General of Hardee's Division.

After a venture in cotton planting, unsuccessful on account of floods in Yazoo Pass, Colonel Pickett resumed the practice of his profession, and, as Chief Engineer, rebuilt the bridges and reconstructed the roadbed for the Memphis and Ohio Railroad Company, now a part of the Louisville and Nashville System.

On April 27th, 1870, Colonel Pickett was married to Miss Theodosia Curd, of Lexington, Ky., who died a year later, leaving a son who survived her only four years.

After the deaths of his wife and little son, Colonel Pickett went West in 1873, and after several years spent in prospecting and fighting Indians over the territory now embraced in the Yellowstone Reservation, he established himself on a cattle ranch in the Big Horn Country, in Wyoming, and became widely known as a successful hunter of the grizzly bear. When this region became populated and prosperous, Colonel Pickett represented his district for several terms in the State Legislature of Wyoming, first as Representative and afterward as Senator.

In 1904, he returned to Kentucky and purchased a home in Lexington, where he lived until his death on March 5th, 1917, in his ninetieth year. Knowing the hopelessness of his case, he met his end like a soldier, calmly and unflinchingly, his last days being disturbed only by the thought of leaving his invalid brother, Major George Blackwell Pickett, who survives him.

A life-long friend, Judge George B. Kinkead, of Lexington, Ky., writes of Colonel Pickett as follows:

"Few knew him intimately, but to many the tall, alert figure of this handsome old gentleman, democratic in his feelings, but displaying the patrician in every lineament, was familiar. In every walk of life, his most striking and distinguishing characteristic was a prompt recognition of every duty imposed, and an unfaltering courage to discharge it. One who lived close to him for years, but a few days since remarked to the writer, 'He was the best neighbor I ever knew.'"

Colonel Pickett was a member of the Boone and Crockett Club, and the Confederate Veterans' Association. He was also a member of Christ Church Cathedral, from which his funeral was held on March 7th, 1917.

He was the oldest living member of the American Society of Civil Engineers and although not present at the meeting of November 5th, 1852, when the Society was organized, he was elected a Member on July 6th, 1853, and therefore might be classed as a Charter Member.

Throughout his long membership, he took a lively interest in the welfare and prosperity of the Society and on all occasions proudly displayed his badge. In 1908, Colonel Pickett, then in his eighty-first year, contributed a discussion on the paper by H. M. Chittenden, M. Am. Soc. C. E., entitled "Forests and Reservoirs in Their Relation to Stream Flow with Particular Reference to Navigable Rivers"*, and also a paper entitled "The Floods of the Mississippi Delta: Their Causes, and Suggestions as to Their Control".† In 1911, Colonel Pickett attended the Annual Convention of the Society, which was held that year at Chattanooga, Tenn.

Colonel Pickett was elected a Member of the American Society of Civil Engineers on July 6th, 1853, and an Honorary Member on April 1st, 1914.

† *Transactions*, Am. Soc. C. E., Vol. LXIII, p. 53

JOHN FERRIS ALDEN, M. Am. Soc. C. E.*

DIED FEBRUARY 27TH, 1917.

John Ferris Alden, the son of Sidney and Harriet Webster Alden, and a direct descendant in the eighth generation of John Alden, of Plymouth, Mass., was born at Cohoes, N. Y., on March 19th, 1852. He was educated in private schools in Albany, N. Y., and at Rensselaer Polytechnic Institute, from which he was graduated with honors, in June, 1872, with the degree of Civil Engineer.

Mr. Alden did his first engineering work as Assistant Engineer on the construction of the railroad bridge to carry the tracks of the New York Central Railroad over the Hudson River at Albany, N. Y., under Mr. Charles Hilton as Chief Engineer.

In January, 1875, Mr. Alden accepted a position as Assistant Engineer at the Leighton Bridge and Iron Works at Rochester, N. Y. In 1877, he was made Chief Engineer and, in 1878, became a member of the firm. On July 1st, 1881, with the late Moritz Lassig, M. Am. Soc. C. E., as partner, he leased the Leighton Bridge and Iron Works and continued the business in Rochester under the name of Alden and Lassig and that in Chicago, Ill., under the name of Lassig and Alden.

In January, 1886, the partnership was dissolved and Mr. Alden purchased the business interests of the firm in Rochester, Mr. Lassig retaining those in Chicago. Mr. Alden then re-organized his business under the name of the Rochester Bridge and Iron Works of which he continued as sole owner until 1901 when he sold out to the American Bridge Company. He retained an interest in the Company, however, until his death.

During his active connection with the Rochester Bridge and Iron Works, Mr. Alden built many steel and iron bridges, especially for railroads, throughout the United States and Canada. Among these may be mentioned the Elevated Railroad in New York City; bridges for the Delaware and Hudson Railroad, the Chicago, Milwaukee and St. Paul Railroad, and the Buffalo, Rochester and Pittsburgh Railroad; the bridge over the Columbia River at Pasco, Wash.; the viaducts at Los Angeles, Cal.; the Upper Suspension Bridge at Niagara Falls; and the Driving Park Avenue Bridge at Rochester, N. Y. He also constructed the tower and elevator in the House of Parliament, at Ottawa, Ont., Canada, as well as many buildings in New York, Chicago, and other cities, and furnished most of the iron and steel work for the buildings of the Columbian Exposition, at Chicago, Ill.

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

Mr. Alden was married, in 1885, to Miss Mary E. Bogue, of Brooklyn, N. Y., who, with two sons and three daughters, survives him.

At the time of his death which occurred at his home at Rochester, N. Y., on February 27th, 1917, after a brief illness, Mr. Alden was President of the Locke Insulator Manufacturing Company and a Director of the Genesee Valley Trust Company. He was also a member of the Rensselaer Society of Civil Engineers, the Rochester Chamber of Commerce, the Alden Kindred of America, the Sons of the Mayflower, the Genesee Valley Club, and the Rochester Club. He was Vice-President of the Board of Trustees of the Friendly Home, and was actively interested in the erection of its new home. He was also a Vestryman and prominent member of Christ (Protestant Episcopal) Church.

Mr. Alden was elected a Member of the American Society of Civil Engineers on July 6th, 1887.

THOMAS APPLETON, M. Am. Soc. C. E.*

DIED AUGUST 3D, 1916.

Thomas Appleton, the son of Edward and Frances Anne Atkinson Appleton, was born at Reading, Mass., on October 13th, 1846. He was of Colonial ancestry, his father's family having settled in Ipswich, Mass., in 1635. His mother was a descendant of Simon Bradstreet, an early Colonial Governor of Massachusetts and New Hampshire, and Anne Dudley.

Mr. Appleton's father, Edward Appleton, was a Civil Engineer, having been graduated from Harvard College in the Class of 1835, and a member of the first Board of Railroad Commissioners of Massachusetts. In 1862, after completing his studies in the public schools of Reading, Thomas Appleton entered the employ of the Boston, Hartford and Erie Railroad as Rodman, continuing with this Company until he enlisted, for the Civil War, in Company E, Eighth Massachusetts Volunteer Infantry, from which he was honorably discharged in November, 1864.

In 1865, Mr. Appleton entered Rensselaer Polytechnic Institute, from which he was graduated with the Class of 1868 with the degree of Civil Engineer. Among his classmates at Rensselaer were M. T. Endicott, Past-President, Am. Soc. C. E., and the late Virgil G. Bogue, L. L. Buck, and O. F. Nichols, Members, Am. Soc. C. E.

After his graduation, Mr. Appleton was appointed Resident Engineer with the Dexter and Newport Railroad Company, on construction work in Maine, and, in 1869, he was made Division Engineer on the Somerset Railroad. In 1870, he was appointed Engineer in charge of the reconstruction of the Troy and Greenfield Railroad (now a part of the Fitchburg Division of the Boston and Maine System) east of the Hoosac Tunnel, in Massachusetts. Recently, the old steel work on this line was replaced to accommodate the heavier loads and train movements of these days, but the abutments of the two bridges across the Deerfield River, constructed under Mr. Appleton's direction, were not disturbed or strengthened.

On the completion of this work, in 1871, Mr. Appleton was appointed Chief Engineer of the Essex Branch and Marginal Freight Railroads in Massachusetts, and, in 1872, he was made Principal Assistant Engineer of the Boston and Maine Railroad.

From 1873 to 1879, he was engaged on surveys for several railroads, and acted as Inspector of Bridges for the City of Boston and also as Traveling Agent for the Niagara Bridge Works, of Buffalo, N. Y.

In 1880, Mr. Appleton was made Superintendent of Bridges and Buildings for the Galveston, Harrisburg and San Antonio Railway

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

(now a part of the Southern Pacific System in Texas) and, in 1881, he was engaged in making location surveys in New York and Connecticut for the New York, Boston, Albany and Schenectady Railroad. He left the latter work to become Chief Engineer of the Kansas and Eastern Construction Company and, in this capacity, built the Leavenworth, Topeka and Southwestern Railroad. In 1883, he was employed as Assistant Engineer on the Topeka, Salina and Western Railroad.

In 1884, Mr. Appleton was appointed City Engineer of East Saginaw, Mich., but preferring railroad work, he resigned to accept the position of Principal Assistant Engineer on the Chicago, Milwaukee and St. Paul Railroad, which he held from 1885 to 1889. He then went to the Union Pacific Railroad where he served as Engineer of Buildings until the latter part of 1890. The late Mr. Bogue, one of his classmates at college, was Chief Engineer of the Union Pacific Railroad at that time, and on hearing of Mr. Appleton's death, he wrote of him as follows: "I always had a great affection for him and always found him a sweet-tempered, kindly-disposed man, who did his duty."

In 1891, Mr. Appleton opened an office in Chicago, Ill., for the private practice of engineering, which he continued until 1895, when he was appointed Engineer of Buildings and Water Supply with the Great Northern Railroad. He resigned this position in 1898 to accept that of Chief Engineer of the Copper Range Railroad.

In 1900, Mr. Appleton entered the Government service as Assistant to the Superintendent of Construction of the United States Life Saving Service, in which capacity he had charge of the construction of many of the life-saving stations along the Atlantic Coast and the Great Lakes.

In 1902, at his own request, Mr. Appleton was transferred from the Life Saving Service to the office of the Supervising Architect, Treasury Department, as Superintendent of Construction, United States Public Buildings, which position he held until his death at Gardiner, Me., on August 3d, 1916. His first work while holding this office was on the construction of the Post Office Building at Creston, Iowa. This was followed by work on public buildings at Holyoke and Northampton, Mass., Wheeling, W. Va., Evanston, Wyo., East St. Louis, Alton, Centralia, and Greenville, Ill., Chelsea, Mass., the new Custom House at Boston, Mass., New Bedford, Mass., and Gardiner, Me. After the earthquake and fire in San Francisco, he was ordered there to assist in the work of temporary repairs to protect Government buildings. The deep and difficult foundations for the new Custom House at Boston, Mass., were constructed under his supervision, but at his request and on account of advancing years, he was relieved from that detail and transferred to New Bedford in 1913.

Mr. Appleton was married to Mary Louise Burnham, of Essex, Mass., on October 1st, 1871, and is survived by his widow, one brother, four sisters, and two stepsons.

He was the founder and first President of the Society of Constructors of Federal Buildings, which was organized, principally through his efforts, in 1910, with the idea of promoting closer relations between the Office and Field forces of the Supervising Architect's Office, and thereby raising the efficiency of both. The success of this organization, which has grown from a few members to include not only the entire Field force of the Office, but also a considerable number of the Office force, is due to Mr. Appleton's never-failing interest and activity in its affairs. He attended all its Annual Conventions and was a generous contributor to the pages of its *Journal,* his last paper, on the history and origin of the Society, having been published in May, 1916.

In 1874, Mr. Appleton joined the Boston Society of Civil Engineers and continued his membership in that organization for many years after going West. He was a charter member of the American Engineering and Maintenance of Way Association (now the American Railway Engineering Association), and while in Chicago, he joined the Western Society of Engineers and served as its Secretary for a year or more. He was also a member of the American Society of Mechanical Engineers from 1893 to 1910, a member of Kilpatrick Post No. 71, G. A. R., of Holyoke, Mass., and of the Zeta Psi Fraternity.

The following extract from a letter from the Acting Supervising Architect, Mr. James A. Wetmore, to the Secretary of the Society of Constructors of Federal Buildings, expresses the high estimate in which Mr. Appleton was held by all who knew him:

"* * * In every relation with him, official and personal, I was impressed with his devotion to duty, his ideals of rectitude and honor, his kindly disposition, and his consideration for others. Endowed with a pleasing personality, possessed of the requisite technical qualifications, gifted with tact and a disposition to find a way to overcome difficulties, it was natural that he should be highly regarded by his associates and co-workers in the Office and in the Field. I feel that in his death, the public service has lost a faithful servant, your Society a devoted adherent, and all of us a sincere friend."

Mr. Appleton's immediate superior, Mr. George O. Von Nerta, Technical Officer of the Supervising Architect's Office, writes:

"* * * Where he stood out apart from the rest was in his ability to conceive and carry into execution an improvement of far-reaching effect."

Mr. Appleton was elected a Member of the American Society of Civil Engineers on April 4th, 1883.

WILLIAM HARRY ARNOLD, M. Am. Soc. C. E.*

DIED AUGUST 13TH, 1917.

William Harry Arnold was born at Smithfield, Pa., on September 22d, 1864. From 1880 to 1883, he was a student at the Mt. Pleasant Classical and Scientific Institute, at Mt. Pleasant, Pa., and from January, 1883, to August, 1885, he served as an Apprentice in the Erecting Shops of the Pennsylvania Railroad at Pittsburgh, Pa.

In September, 1885, Mr. Arnold entered Rensselaer Polytechnic Institute, at Troy, N. Y., from which he was graduated in June, 1890, with the degree of C. E., having lost one year (1886), on account of sickness.

In June, 1890, he entered the employ of Nier and Hartford, of Chattanooga, Tenn., being engaged on general engineering work. He remained in this position and with Hartford and Hebert, until June, 1891, when he was engaged by G. W. G. Ferris and Company, of Pittsburgh, Pa., on general inspection work.

From April to September, 1895, Mr. Arnold served with the Barber Asphalt Company, of Buffalo, N. Y., and then came to New York City, as Office Manager for R. W. Hildreth and Company. He also had charge of the field work for this Company in the vicinity of New York.

From August, 1896, to April, 1899, Mr. Arnold was engaged with various officers of the Corps of Engineers, U. S. A., generally around New York City, first as Draftsman, and then as Inspector of harbor improvements. This work included the Patchogue Jetty improvement, the dredging of the South Amboy, N. J., Channel, the dredging of the Bay Ridge and Red Hook Channels, New York Harbor, as well as work in connection with battery emplacements at Fort Wadsworth, N. Y., and Fort Taylor, at Key West, Fla.

In April, 1899, Mr. Arnold entered the employ of the W. H. Beard Dredging Company, of New York City, as Superintendent and Engineer, in complete charge of the dredging fleet and the reconstruction of dredges and tugs, retaining this position until July, 1903, when he became Superintendent of the fleet of the Hughes Brothers and Bangs Dredging Company, of New York City.

From July to October, 1904, Mr. Arnold was employed by J. G. White and Company, of New York City, on harbor work in the Philippine Islands.

In March, 1905, he was engaged by the Bush Terminal Company, of New York City, first as Superintendent of Floating Equipment,

* Memoir prepared by the Secretary from information furnished by E. B. Ashby, Cons. Engr., Lehigh Valley Railroad Company.

including the design and construction of tugs, car floats, dredges, etc., until June, 1906, when he was made Chief Engineer of the Company.

In 1907, Mr. Arnold resigned his position with the Bush Terminal Company to enter into private practice as a member of the firm of Arnold and Andrew, Consulting Engineers, but, in 1909, the partnership was dissolved, and Mr. Arnold became General Manager of the Bay State Dredging Company, of Boston, Mass.

From 1912 until January, 1914, he was engaged in general engineering work. On the latter date he was appointed Terminal Engineer of the Lehigh Valley Railroad Company, in New York City, which position he retained until his death, on August 13th, 1917. In this capacity, Mr. Arnold had charge of the construction of the new ore dock at Constable Hook, N. J., as well as the piers, pier sheds, and dredging in New York Harbor and at Perth Amboy, N. J.

Mr. Arnold was elected a Member of the American Society of Civil Engineers on May 1st, 1907.

EDWARD MANNING BIGELOW, M. Am. Soc. C. E.*

DIED DECEMBER 6TH, 1916.

Edward Manning Bigelow was born in Pittsburgh, Pa., on November 6th, 1850, being one of five children born to Edward M. and Mary Steel Bigelow. He received his early education in the public schools and after graduation entered the Western University of Pennsylvania (now the University of Pittsburgh) where he studied civil engineering.

Upon leaving college he entered the service of the City of Pittsburgh in a subordinate position on the staff of the City Engineer, which position he held until 1874 when he was promoted to engineer in charge of certain street construction, working under a Commission which was authorized by special legislative enactment. Subsequently, the laws authorizing this work were declared unconstitutional, and Mr. Bigelow left the service of the City for a short time. He was re-employed by the City and served as Assistant Engineer in charge of surveys and the location of streets from 1876 to 1878, and in charge of construction from 1878 to 1882.

On January 9th, 1882, he was unanimously elected City Engineer by Council, which position he held until 1885, and from 1885 to 1888 he was City Engineer and Commissioner of Highways. At this time the City Charter was changed, the Department of Public Works being created, and Mr. Bigelow was then appointed Director of the Department of Public Works, which office he held for two full terms of three years each.

On June 1st, 1911, Governor John K. Tener of Pennsylvania appointed Mr. Bigelow to the office of State Commissioner of Highways, which office he held until April, 1915. Mr. Bigelow was honored by a re-appointment to the office of Director of the Department of Public Works of Pittsburgh just prior to his death.

Mr. Bigelow's entire life was devoted to municipal improvements. He was an engineer of broad vision and foresight; his plans for improvements were always comprehensive, and provided well for the future. Under his supervision many miles of Pittsburgh's streets and sewers were laid out and constructed, including the boulevards. His greatest achievement, and the one in which he took the most pride, was the development of Highland and Schenley Parks. It was also under his administration that work on the water purification plant was started.

Mr. Bigelow was an honest, tireless, and conscientious worker, and more than ordinary credit is due him from the people of Pittsburgh

* Memoir prepared by N. S. Sprague, M. Am. Soc. C. E.

when it is considered that many of the improvements which he inaugurated and carried through to successful completion were consummated in the face of much criticism and abuse. The appreciation of his services in the development of the parks was manifest by the erection of a bronze statue placed at the entrance of Schenley Park, the cost of which was defrayed by public subscription. He was known as the "Father of the Parks".

The same characteristic plan on a large and comprehensive scale was displayed by Mr. Bigelow during his tenure of office as Commissioner of Highways of the State of Pennsylvania. Under his direction plans were made for the improvement of a comprehensive system of highways traversing the State in anticipation of securing funds for their improvement. Many of the State highways were improved, and much credit is due to him for the creditable work performed with the limited funds at his disposal.

Even during periods when Mr. Bigelow was not connected with the government of Pittsburgh, his interest in city affairs never ceased; and his genius for planning and energy in advocating improvements for the benefit of the city were always manifest.

Aside from Mr. Bigelow's professional career, he was a man of affairs and took an active interest in financial, commercial, and social activities. He was a Trustee of the Carnegie Institute of Technology from the time of its founding, and took an active part in the development of this institution. He was President of the Liberty National Bank, the Liberty Savings Bank, and the Homewood Cemetery. He was also a Trustee of Andrew Carnegie's benefactions, the Carnegie Library and Institute, Carnegie Hero Fund Commission, the Institute of Technology, and also of the Schenley Memorial Commission. He was a member of, and also took an active part in, the East Liberty Presbyterian Church, and his time and talents were given freely in the raising of funds and for other purposes connected with this church.

Upon Mr. Bigelow's death, the Council of the City of Pittsburgh paid due respect by calling a special meeting of that body for the purpose of honoring the memory of the late Director of the Department of Public Works, and the following resolution was passed, which perhaps is the best expression of the high regard and esteem in which his services to the City of Pittsburgh are held by this community:

"*Whereas,* Almighty God, in His infinite wisdom, has seen fit to remove from our midst one of Pittsburgh's most distinguished citizens; and

"*Whereas,* Edward Manning Bigelow was a man of stainless integrity, of superb courage, and of great intellectual force; a man who always walked in the highway of right; and in disaster stood erect; a man to whom defeat was but a spur to further effort; a man who

believed in the loyalty to man, in the sovereignty of the citizen, and in the matchless greatness of this grand City; a man who gave freely of his talents and genius to the up-building of the City of Pittsburgh, who served the City for many years with a self-sacrificing devotion, and whose master hand is indelibly impressed upon every section of the City; and

Whereas, As he lived he died, with that tenacity of purpose which characterized his life; while yet in love with life and raptured with the world he bravely answered the call of the Master of the Universe and passed to his eternal home beyond the utmost reach of human harm or help. He has left with us his wealth of thought and deed—the memory of a brave, imperious, honest man, who bowed alone to death; therefore be it

Resolved, that a copy of these resolutions be spread upon the Minutes of Council of Pittsburgh, and that a copy be sent to his bereaved widow."

In addition to the foregoing resolution, many tributes of respect were paid to Mr. Bigelow's ability as a citizen and public officer by men prominently identified with the financial, commercial, and professional affairs of the City.

Mr. Bigelow was elected a Member of the American Society of Civil Engineers on December 4th, 1889.

DANIEL WHEELER BOWMAN, M. Am. Soc. C. E.*

DIED MARCH 14TH, 1917.

Daniel Wheeler Bowman, the son of Quaker parents, Francis Bowman and Elizabeth (Hammond) Bowman, was born in New Bedford, Mass., on October 2d, 1844. In 1857 his parents purchased a farm at Ledyard, Cayuga County, N. Y., and moved there. Mr. Bowman spent much time on this farm, lending to his life the enthusiasm and interest which marked him throughout his later years. There he acquired and developed his great love for Nature and growing things; and this clung to him until his death.

He received his early education at Oakwood Seminary, Union Springs, N. Y., from which he was graduated in 1865. He returned and took a post-graduate course at the Seminary, on finishing which he was given charge of a Friends Academy, in Ohio. In 1868, Mr. Bowman went to Kansas on some survey work, returning the same year to enter Cornell University where he took the Civil Engineering Course. His life at Cornell was characteristic of the man: simple, honest, and earnest. With an unusually alert mind and great application, he stood very high in all his classes, and by his native kindness and interest in his fellows and in all that pertained to the general welfare, he endeared himself to his classmates and all who knew him. He was graduated in 1872 in the first "through" class in Civil Engineering. In 1883, Cornell University conferred on him the degree of C. E.

Immediately after his graduation, Mr. Bowman was offered a position as Instrumentman on some survey work for the New York Central Railroad Company in New York State, which he accepted, and in which position he continued for two years, resigning to become associated as Engineering Secretary to the late Capt. James B. Eads, M. Am. Soc. C. E., who at that time was in charge of important jetty work at the Southwest Pass of the Mississippi River. While on this work, Mr. Bowman was directly under the late G. W. R. Bayley, M. Am. Soc. C. E., and was sent to New York City and Washington, D. C., on special missions in connection with his work. He also had charge of the construction of the dredge, *G. W. R. Bayley,* in Pittsburgh, Pa., in 1877, for use on the jetty work. At that time it was the largest dredge built, and was an engineering triumph. While on this work Mr. Bowman married Ida Portia, the daughter of Mr. Bayley. Two sons and a daughter by this marriage survive him.

* Memoir prepared by N. R. McLure, M. Am. Soc. C. E., with the assistance of Seymour P. Thomas, Esq.

After this work was finished, Mr. Bowman made some very extensive computations for a proposed bridge across the East River at Blackwell's Island, New York City, for Capt. Eads, in connection with the competition then asked for by those contemplating this structure. His ability as a Designing Engineer on this work was so marked that he was sent by Capt. Eads to Phœnixville, Pa., in connection with some work that was then being done for him by Clarke, Reeves and Company (now The Phœnix Bridge Company). At that time the late Adolphus Bonzano, M. Am. Soc. C. E., was Chief Engineer of this concern, and was so attracted by the quick perception, ability to grasp and solve difficult situations, and general engineering ability of young Bowman, that he arranged for him to remain at Phœnixville as his Assistant, in charge of estimating and designing. While in this position Mr. Bowman designed the first Kinzua Viaduct, for the New York, Lake Erie and Western Railroad Company, in McKean County, Pa., which, at that time, was one of the longest and highest railroad viaducts in the world. He designed the Albany and Greenbush Bridge across the Hudson River, at Albany, N. Y., a double-deck structure carrying railroad and roadway, with approach spans and a rim-bearing draw-span. He also designed the difficult reverse curve on the New York Elevated Railway work, at 110th Street, Boulevard Crossing. This was built with Phœnix columns and latticed girders, and, at the time, was considered quite a complicated structure. Another notable bridge designed by Mr. Bowman at this period was that over Rondout Creek, on the West Shore Railroad.

In 1885, Mr. Bowman resigned his position as Designing Engineer of The Phœnix Bridge Company and went South, doing some bridge inspection work for the Southern Railway, and, in 1888, he was made Bridge Engineer for the Central of Georgia Railway. While in this position he had charge of the rebuilding of many of the old bridges on the line. In 1891, he was made Assistant Engineer of The Boston Bridge Works, at Boston, Mass., which position he filled until 1894, when he returned to Phœnixville, Pa., as Assistant Engineer for The Phœnix Iron Company. In 1896, he went to Chicago, Ill., with several associates, and organized the Universal Construction Company, of which he became Chief Engineer. In 1897, he again returned to Phœnixville as Assistant Engineer for The Phœnix Iron Company, under H. H. Quimby, M. Am. Soc. C. E., then Chief Engineer. On the resignation of Mr. Quimby from this Company in November, 1900, Mr. Bowman succeeded him as Chief Engineer, in charge of the estimating, computing, designing, detailing, and erection of the structural steel fabricated by The Phœnix Iron Company. He continued as Chief Engineer until February, 1914, when he was made Consulting Engineer, which position he held at the time of his death.

In 1899 he was married to M. Virginia Vanderslice, of Phœnixville, Pa. The years of Mr. Bowman's best service were devoted to structural steel, particularly as applied to bridge and building work, and there are few localities of size in the eastern section of the United States which have not, however unconsciously, felt the influence of his ability through structures erected in their midst. These were improved in construction by his ever watchful and able supervision of the design.

Mr. Bowman was broad and liberal in his views of life, a progressive in more than one sense of the word, charitable in his nature, and a friend and counsellor to those who sought his help and advice. Many a young engineer has been started on the right path through his careful and painstaking efforts in his behalf. He was a great lover of Nature, and spent many days in his later life, in the open among his flowers and fruit trees. He had an intense and loyal affection for Cornell, his Alma Mater, and seldom missed returning at Commencement time to renew his youth with the younger Alumni. Among a host of friends and acquaintances, rarely was there a man who will be so sadly missed.

Mr. Bowman was elected a Member of the American Society of Civil Engineers, on December 3d, 1912.

CHARLES ADOLPHUS CALDWELL, M. Am. Soc. C. E.*

DIED AUGUST 31ST, 1916.

Charles Adolphus Caldwell, the son of Oscar Adolphus Caldwell and Carrie B. Caldwell, was born in Macon, Bibb County, Ga., on October 18th, 1866.

He began his engineering studies in 1882 at Vanderbilt University where he remained two years. In 1884, he entered Rensselaer Polytechnic Institute, Troy, N. Y., and was graduated in 1888 with the degree of C. E.

Shortly afterward Mr. Caldwell began his professional career under F. T. Dabney, Chief Engineer of the Central of Georgia Railroad, on the extension of this road from Savannah to Americus.

In 1890, he was made Assistant Engineer on the St. Augustine and North Beach Railroad, in Florida, from which position he resigned to return to Macon, to accept an appointment in the office of the City Engineer. In 1894 he was associated with Capt. J. W. Wilcox, Assistant Engineer on the construction of the Fort Valley Water-Works, and as Principal Assistant to the City Engineer on the construction of 32 miles of sanitary sewers in Macon, Ga.

In 1898, he was the Principal Assistant Engineer, in charge of construction work, for the Macon Gas Light and Water Company, during the construction of a 5 000 000-gal. filter plant and a new pumping station.

In 1899, Mr. Caldwell designed and supervised the sanitary sewer system for the City of Valdosta, Ga., and, in the same year, as Chief Engineer, designed and constructed a water-power development for 1 000 h.p., at Juliet, Ga., on the Ocmulgee River. Here he also built a 3 000-spindle cotton mill, and a grist mill with a daily capacity of 8 000 bushels for the Juliet Milling Company.

From 1899 to 1907, he was engaged in the general practice of his profession, with offices at Macon, Ga. During this time, he had charge of a large amount of general engineering work, including a number of highway bridges, a sanitary sewer system for Forsyth, Ga., and was associated with J. N. Hazlehurst, M. Am. Soc. C. E., in making the appraisal of the existing water-works property of the Macon Gas Light and Water Company, and designing a proposed municipal water-works system of 10 000 000 gal. daily capacity. In 1910, he and Mr. Hazlehurst represented the City of Macon before the Board of Arbitration which fixed the value of this property at $699 000, when the plant was purchased by the City.

* Memoir prepared by G. R. Solomon, M. Am. Soc. C. E.

In 1911, Mr. Caldwell prepared reports and plans on a 10 000-h.p. hydro-electric development on the Ocmulgee River, near Juliet, and was also engaged, as Chief Engineer, on the remodeling and extension of the water-works system of the City of Macon.

In addition to his engineering work, Mr. Caldwell was interested in several manufacturing concerns as an officer and decorator, and his opinion was always sought and valued because of his fair-mindedness. He was universally liked and trusted, and his death is a decided loss to the Profession.

He was unmarried, and is survived by one sister, Mrs. John B. Birch, of Macon, Ga.

Mr. Caldwell was elected a Member of the American Society of Civil Engineers, on September 5th, 1911.

EDWARD CANFIELD, M. Am. Soc. C. E.*

DIED AUGUST 18TH, 1916.

Edward Canfield, son of Caleb Augustus and Sarah Withington Canfield, was born at Geneva, N. Y., on May 27th, 1848. He was graduated from Hobart College in 1869, receiving the degree of A. B., and, in 1874, the degree of A. M.

In 1869, Mr. Canfield began his professional career in the Engineering Corps of the Erie and Geneva Valley Railroad. From 1870 to 1872, he was Division Engineer of the Syracuse Northern Railroad; from 1872 to 1873, Division Engineer of the Pennsylvania Petroleum Railroad; from 1873 to 1874, Assistant Engineer, Atlantic and Great Western Railway; from 1875 to 1878, Division Engineer of the Syracuse, Geneva and Corning Railroad; from 1879 to 1881, Assistant Engineer of the New York, Lake Erie and Western Railroad; and from 1881 to 1882, Roadmaster of the Rochester Division of the New York, Lake Erie and Western Railroad. While in the latter position, he organized and carried out the work of changing the entire Rochester Division from broad to standard gauge in one day.

On November 9th, 1882, Mr. Canfield entered the service of the New York, Ontario and Western Railway Company, in which he continued to the close of his life, having been first appointed Superintendent of Construction of the line from Middletown to Cornwall, N. Y., and from there to Weehawken, N. J., the latter portion being now a part of the West Shore Railroad, which is leased to and operated by the New York Central Railroad Company. In 1884, on the completion of the construction work, he was appointed Superintendent of the Southern Division.

On December 1st, 1887, he was appointed Chief Engineer in charge of new construction, maintenance of way, and bridges and buildings. As Chief Engineer, he had charge of locating and constructing the branch from Cadosia, N. Y., to Scranton, Pa., which gave the New York, Ontario and Western Railway Company entrance into the anthracite coal regions of Pennsylvania. In 1895, he was appointed General Superintendent, having charge of all operation except traffic, which office he held at the time of his death.

Mr. Canfield served for some years on the Board of Directors of the Orange County Trust Company, was, at the time of his death, a Trustee of the Middletown Savings Bank, and, at one time, a member of the Board of Education of Middletown, N. Y.

* Memoir prepared by J. H. Nuelle, Esq.

The Board of Directors of the New York, Ontario and Western Railway Company adopted the following minute at a meeting held September 12th, 1916:

"This Board records its deep sense of loss in the death of Edward Canfield, late General Superintendent, which occurred at his home in Middletown, New York, on August 18, 1916.

"Mr. Canfield entered the service in 1882 in the Engineering Department, later becoming Chief Engineer, and in 1895 General Superintendent.

"In all his long service he displayed intense loyalty to the Company and its interests; to his skill as an engineer is due in large part the continued progressive advance in the physical condition of the property, while through his good judgment and careful management a high degree of efficiency in operation has been attained.

"His fine character, marked ability, untiring industry, absolute devotion to duty, and unfailing justice in his relations with all in the service, gained for him the profound respect and regard of all who knew him.

"No better example could be found in railroad service than the record of his life work."

He was married on September 17th, 1874, to Jane Hastings, daughter of Major David H. Hastings, of the United States Army, who, with their sons, David H. Canfield, Captain Edward Canfield, U. S. A., and Richard W. Canfield, survives him.

Mr. Canfield was a member of the Sigma Phi Fraternity, and was elected a Member of the American Society of Civil Engineers on December 3d, 1879.

ANDREW CHASE CUNNINGHAM, M. Am. Soc. C. E.*

DIED JANUARY 13TH, 1917.

Andrew Chase Cunningham, the son of Thomas and Celeste (Chase) Cunningham, was born at Mohawk, N. Y., on February 15th, 1858.

He was appointed to the United States Naval Academy from the Twenty-first District of New York State, on June 9th, 1874, and was graduated from that institution as a Midshipman on June 10th, 1879. He served on the U. S. S. *Shenandoah* and the U. S. S. *Saratoga*, and on February 1st, 1883, he resigned from the service, meanwhile having been promoted to the rank of Ensign. Mr. Cunningham had decided by this time that a career in the Navy was not what he desired, and, having determined to become a Civil Engineer, he entered Rensselaer Polytechnic Institute, at Troy, N. Y., from which he was graduated in 1885 with the degree of Civil Engineer.

From October, 1885, to April, 1886, Mr. Cunningham occupied the position of Topographer on preliminary and location surveys of the Lincoln Branch of the Missouri-Pacific Railway, and from May, 1886, to September, 1887, he served as Draftsman with the Massillon Bridge Company, Massillon, Ohio. From September, 1887, to November, 1890, he was in charge of the inspection of iron and steel in Pittsburgh, Pa., and vicinity. This work consisted in the acceptance or rejection of material for such structures as the high bridge across the Mississippi River, at St. Paul, Minn., the Ohio Connection Bridge across the river below Pittsburgh, the New York Elevated Railway, numerous large buildings in Chicago, Ill., and bridges on the Lake Shore and Michigan Southern Railway, the Pennsylvania System, the Louisville and Nashville, and other railroads.

From November, 1890, to May, 1892, Mr. Cunningham was Chief Inspector for Carnegie, Phipps and Company, of Pittsburgh, Pa., now the Carnegie Steel Company. In this position he had charge of the testing and inspection of steel materials, together with special investigation and special supervision of material for several structures, such as the Memphis Bridge, the Sixth Street Bridge across the Allegheny River at Pittsburgh, and others.

In May, 1892, Mr. Cunningham associated himself with Charles F. Stowell, M. Am. Soc. C. E., at Albany, N. Y., under the firm name of Stowell and Cunningham, the principal engineering business of the company being in connection with the design, inspection, and testing of steel bridges and steel materials. This work included materials and bridges for the New York Central and Hudson River Railroad, and the Central Vermont Railroad, as well as materials for the Cities of

* Memoir prepared by F. T. Chambers, M. Am. Soc. C. E.

Albany, N. Y., Waterbury, Conn., for the State Engineer of New York, and the U. S. Treasury Department. In 1898, while he was a member of this firm, the Spanish War broke out, and, as a former officer of the Navy, he obeyed his country's call, volunteering for such duty as he might be assigned to by the Navy Department. At that time the Navy was by no means as large as it is now, and had almost no auxiliary ships for the purpose of furnishing supplies to the fleet. Mr. Cunningham, therefore, found himself an Ensign, on May 14th, 1898, aboard the Collier *Abarenda*, a ship purchased for that use. While this ship was moored to the wharf at the New York Navy Yard, the late L. L. Buck, M. Am. Soc. C. E., visited the Navy Yard for consultation work, in connection with one of the dry docks then under repair. Some one had informed him that Mr. Cunningham was serving as an Ensign aboard the collier, and Mr. Buck expressed the determination to visit him before he left the yard, adding at the same time that he considered Mr. Cunningham one of the foremost steel experts of the country, and that it seemed to him a waste of valuable services to have placed him as an Ensign aboard a supply ship. Mr. Cunningham's nature was such that he would never have sought to be transferred from this position, but Mr. Buck felt strongly on the subject, and made it his business to inform the Navy Department of his views, the consequence being that on May 21st, 1898, Mr. Cunningham was transferred to the Bureau of Ordnance, and was immediately assigned to the Washington Navy Yard, which is the Naval gun factory. Mr. Buck and Rear-Admiral Mordecai T. Endicott, U. S. N. (*Retired*), Past-President. Am. Soc. C. E., were classmates at Rensselaer Polytechnic Institute, and it was not long before Admiral Endicott, then Chief of the Bureau of Yards and Docks, learned that an accomplished Civil Engineer was available for naval duty, and, consequently, Mr. Cunningham was transferred to the Bureau of Yards and Docks on June 27th, 1898. The Civil Engineer Corps of the Navy was then rapidly expanding and in need of officers, and Mr. Cunningham served first on a board to examine candidates for the position of Civil Engineer in the Navy; before the successful candidates were appointed, however, he himself, on September 29th, 1898, was given a permanent commission. On October 5th of that year, he reported to the Bureau of Yards and Docks, where he served until November 6th, 1901, being then detached and ordered to the Naval Station, New Orleans, La. This was a new station just being established, and Mr. Cunningham was the first Civil Engineer officer, thus being given the opportunity to lay out the engineering works from the start. On April 3d, 1903, he was detached from the New Orleans Station and ordered to the Naval Academy, where he served until June 9th, 1905, and from there he was again ordered to the Bureau of Yards and Docks. On March 17th,

1906, he was commissioned with the rank of Lieutenant in the Corps of Civil Engineers.

Mr. Cunningham continued to serve in the Bureau of Yards and Docks as Principal Assistant to Admiral Endicott until April 6th, 1907, when he was ordered to the Navy Yard, Norfolk, Va., as Senior Civil Engineer Officer, and on November 18th, 1909, he was commissioned with the rank of Lieutenant Commander. On February 20th, 1910, he was detached from the Norfolk Navy Yard, and ordered to the Navy Department, Washington, D. C., as Inspector of Public Works for the entire Navy. This duty required great tact and diplomacy, and it was on this account that Mr. Cunningham was selected for the work, which necessitated his maintaining headquarters in Washington, and visiting the various Navy Yards, keeping the Department informed as to the status of the various public works, and co-ordinating the ideas of the Yards with those of the Department.

On July 10th, 1913, Mr. Cunningham left headquarters at Washington to assume the duties of Public Works Officer of the Navy Yard, Portsmouth, N. H. Shortly afterward he had a severe nervous breakdown, and on November 17th, 1913, was ordered to sick leave, and did not return to actual duty until June 16th, 1914. He never fully recovered from this illness, although he performed lighter duties practically up to the time of his death, his principal assignments after this being at the Naval Training Station, Great Lakes, Ill., and the Naval Radio Station, Point Isabel, Tex., at both of which places he erected large steel towers for radio-telegraphy.

While on duty in the Bureau of Yards and Docks of the Navy Department, and previous to his detail as Civil Engineer Officer at New Orleans, Mr. Cunningham had supervised the construction of the 16 000-ton steel floating dock for the New Orleans Station. He became much interested in docks of this type, and, at a later date, obtained letters patent on a floating dock of his own invention. He was, indeed, of an inventive turn of mind and secured patents on several of his ideas, one of the best known in the Navy being that for a coal-tar paint.

Mr. Cunningham was affectionately known as "Andy" by his friends and associates, and was universally liked. His genial nature, combined with his diplomatic spirit, caused him to be much in demand on boards of officers for the adjustment of disputes or for changes in contracts.

While at the Naval Academy, he was the champion fencer of his time, and he maintained his interest in this sport up to the time of his severe illness. While in Washington he was a member of the Washington Fencers Club, and when he was at the Navy Yards he stirred the younger men to a revival of the fencing game. He was looked on by the entire Navy as an authority on this subject, and was also consulted by the Army at one time, in connection with the modification

of the Army saber. As a fencer, he was also interested in singlestick, and was the author of a book entitled "The Cane as a Weapon." Fencing was a considerable feature of his recreation; he was also very fond of writing, and contributed various articles to the press, among them being several on naval matters published by the Naval Institute.

Mr. Cunningham was married, at Middleville, N. Y., on June 18th, 1879, to Miss Jessie E. Thomas. He is survived by his widow and two sons: John Howard Cunningham of Grand-Mère, Canada, and George Thomas Cunningham, of Washington, D. C.

Mr. Cunningham was elected an Associate Member of the American Society of Civil Engineers on September 2d, 1891, and a Member on October 3d, 1894.

DAVID WEST CUNNINGHAM, M. Am. Soc. C. E.*

DIED MAY 11TH, 1916.

David West Cunningham, the son of Andrew and Abigail Leonard (West) Cunningham, was born on December 24th, 1829, in Boston, Mass. He was educated at Chauncy Hall School and the Lawrence Scientific School of Harvard University.

In 1848, Mr. Cunningham received an appointment in the Engineering Corps of the Boston Water-works, then building the Cochituate Aqueduct. In 1849, he was on railroad work on the Manchester and Lawrence Railroad and the Sullivan Railroad of the Connecticut River, from which he was transferred to the Ogdensburg and Lake Champlain Railroad. He was stationed first at Moline and afterward at Lawrenceville on the Moira Sub-division, and rode on the first locomotive through to Ogdensburg, which was driven by Mr. Charles L. Schlatter, then Chief Engineer. He was then employed on railroad work in Canada. The eastern half of the Ogdensburg and Lake Champlain Railroad at that time ran through primitive forest, and while at this work, he contracted inflammatory rheumatism which affected his eyes, and he was compelled to give up engineering work for the time being. In 1851, he joined a friend who was a merchant at Cienfuegos, Cuba, and sailed from Boston for Spain early in June, arriving at Cadiz in 24 days.

After 6 months' travel in Europe, Mr. Cunningham entered the Lawrence Scientific School at Harvard, for a course in Civil Engineering, and was graduated as a Civil Engineer.

Mr. Cunningham spent six years in Chili, on railroad and government work, but left to be married. He never returned to that country, on account of his wife's preference for the United States. After leaving Chili, he operated a plantation in Texas.

After the Civil War Mr. Cunningham was engaged in the construction of the Charleston, Mass., Water-works, the Lowell Water-works, and the sewerage systems of Lowell, Mass., and Stillwater, Minn. He was Chief Assistant Engineer for the Boston Water-works. He built the Tarkio Valley (Missouri) Railroad, and later was Consulting Engineer for the Minneapolis Water-works.

Mr. Cunningham then worked a large wheat farm in North Dakota until 1894, at which time he removed to California.

He was married in 1859 to Mary B. S. Fuller, of Boston, who died in 1869. In 1873, he was married to Caroline Smith Thomas, who died at Los Angeles, Cal., in 1910. In 1913, he was married to Minnie A. Holderbaum, at Santa Ana, Cal.

* Memoir prepared by Frank H. Olmsted, M. Am. Soc. C. E.

Mr. Cunningham was a man of high scientific attainments, and naturally a builder. He was favorably known wherever his duties carried him. He was genial in disposition, loved his friends, and had few, if any, enemies. He could without doubt have reached a high position had he remained in the Profession and not digressed at one or two periods in his career to other kinds of work. He was a remarkably well read man, and spoke and wrote fine English. He was also an excellent Spanish scholar, and a valued member of the various scientific bodies to which he belonged.

Mr. Cunningham was a member of the Architects and Engineers' Association of Southern California. He was elected a Member of the American Society of Civil Engineers on May 7th, 1873.

EDMUND HAZEN DRURY, M. Am. Soc. C. E.*

DIED JANUARY 31ST, 1917.

Edmund Hazen Drury was born at St. John, New Brunswick, on July 31st, 1859. He was graduated with honor from the Royal Military College, Kingston, Ont., in June, 1881, and immediately joined the Engineering Staff of the Canadian Pacific Railway Company, continuing thereon until 1888, first as Rodman and finally as Division Engineer.

From 1889 to 1890 Mr. Drury served as Assistant Engineer on railway surveys for the Dominion Government in New Brunswick, and from 1890 to 1893, he was Division Engineer and Acting Chief Engineer on the McLeod Branch of the Calgary, Edmonton, and McLeod Railway.

From 1893 to 1906, he held the following positions: Chief Engineer and Manager of Construction for the contractors of the Quebec Central Railway, 1893-95; Division Engineer on the Canadian Northern Railway, 1895-97; Division Engineer on the Bangor and Aroostook Railway, 1897-98; Assistant Chief Engineer on the Canadian Northern Railway, 1898-1900; Assistant Chief Engineer, Cuba Company Railway, Cuba, 1900-02; Assistant Chief Engineer, Algoma Central Railway, 1902-03; Division Engineer, Crow's Nest Pass Branch, Canadian Pacific Railway Company, 1903-05; and Division Engineer, Canadian Northern Manitoba South Eastern Railway, 1905-06.

Mr. Drury then went to Mexico where he was employed as Auditing Engineer and Assistant Chief Engineer in charge for the Mexican Light and Power Company, Mexico, in Necaxa and the City of Mexico, from 1906 to 1908.

In the autumn of 1908, he was appointed, by the Department of Railways and Canals of Canada, Engineer in charge of exploration and the reconnaissance survey of alternative routes to Port Churchill and Port Nelson on Hudson Bay. His report, which was an able and comprehensive one, was concluded and handed in toward the end of 1909.

In 1910, he was appointed Chief Engineer of the Quebec and Sherbrooke Railway, which position he held until 1911, when he was engaged to prepare an estimate and report for a proposed railway from Edmonton, Alberta, to Bella Coola, on the Pacific Coast of British Columbia, *via* the Pine River Pass, Rocky Mountains, for the Edmonton, Dunvegan, and Pine Pass Railway Company.

Mr. Drury then went to South America as Chief Engineer and Manager of Construction of the Chili Longitudinal Railway, Chili, from 1911 to 1913. It was while conducting this work, through the

* Memoir prepared by E. J. Walsh, Esq.

arid nitrate district of Chili, that his health became impaired. Returning to Canada, in the autumn of 1913, he entered into a general consulting engineering partnership (in the firm of Walsh and Drury, Consulting Engineers), with an office at Ottawa, Ont.

From the latter part of 1914 to the time of his sudden death on January 31st, 1917, Major Drury had served as Acting Assistant Director General of Engineer Services, for the Department of Militia and Defence, at Ottawa.

Major Drury stood in the forefront of the profession as a Railway Engineer. He was a man of high character and unswerving integrity, and neither in private nor public affairs would he deviate from the conscientious discharge of life's duties. Kindly and courteous to a degree, he will be greatly missed by those of his confreres and others who were intimate with him.

Major Drury was a Member of the Canadian Society of Civil Engineers, and was elected a Member of the American Society of Civil Engineers on October 4th, 1905.

AUGUSTUS JAY DuBOIS, M. Am. Soc. C. E.*

DIED OCTOBER 19TH, 1915.

Augustus Jay DuBois, the son of Henry Augustus DuBois and Catherine Helena (Jay) DuBois, who had six other children, was born at Newton Falls, Ohio, on April 25th, 1849. His father, who was of French Huguenot descent, received the degree of M.D. from Columbia College in 1830 and spent most of his life in the practice of medicine. His mother was a granddaughter of Chief Justice John Jay, who was also of French Huguenot descent.

Mr. DuBois prepared for college at the Hopkins Grammar School in New Haven, Conn., and then took the course in Civil Engineering at the Sheffield Scientific School of Yale University, from which he was graduated in 1869. Continuing there in advanced studies, he secured the degree of C. E. in 1870 and that of Ph.D. in 1873. He then spent 18 months at the Royal Mining Academy in Freiberg, Saxony, followed by a few months of surveying work in California and Connecticut.

During 1871-75 he made a special study of the then new science of Graphic Statics, the results of which were published in 1875, in two volumes, under the title "Elements of Graphical Statics and Their Application to Framed Structures." This was the first comprehensive work on the subject which appeared in the United States, and it was re-issued in revised editions in 1877, 1879, and 1883.

In 1875, Mr. DuBois was appointed Professor of Civil and Mechanical Engineering in Lehigh University, from which he was called, in 1877, to the chair of Mechanical Engineering at the Sheffield Scientific School, and, in 1884, he was appointed Professor of Civil Engineering there, a position which he filled until his death.

During his forty years of service as a teacher of Engineering, Professor DuBois was active in enriching the theory of the subject. He translated from the fourth edition of Weisbach's "Mechanics of Engineering", the sections "Hydraulics and Hydraulic Motors" (published in 1877), and "Theory of the Steam Engine" (1877); also Weyrauch's "Calculation of Iron and Steel Constructions" (1877), and Roentgen's "Principles of Thermodynamics" (1879). These books were issued at a time when literature on these subjects was scanty in the United States, and they were used extensively in engineering schools and by engineers, each of them passing through several editions. In 1883 appeared the first edition of his "Stresses in Framed Structures," a book in quarto form, which gave methods of computing stresses by

* Memoir prepared by Mansfield Merriman, M. Am. Soc. C. E.

both analytic and graphic processes and also contained fifteen folding plates of designs and working drawings of bridges. This book was widely used as a text in engineering schools, and it passed through twelve editions, each being revised and improved. The manuscript for an enlarged edition was completed shortly before his death.

In 1894 and 1895 there appeared three octavo volumes by Professor DuBois, entitled "Elementary Principles of Mechanics", one treating of kinematics, another of statics, and a third of kinetics. In 1901, these volumes were re-issued in revised quarto form as the first volume of "Mechanics of Engineering", the second volume being the twelfth edition of his "Stresses in Framed Structures."

Professor DuBois had contributed papers on roof trusses, retaining walls, and the steam engine to the technical journals; he had also taken part in discussions before the Society on flexure of beams, and had contributed papers on "The Weights of Bridges"* and on "The Strength of Columns".†

During 1889-94 he prepared and delivered six lectures entitled "Science and Faith", "Science and Immortality", "Science and Miracle", etc., which were published in the *Century Magazine* and other periodicals. These lectures were marked by originality of thought and beauty of style, and by the purpose to establish moral truths on the fundamental principles of mechanics; one of the last products of his pen was to summarize the conclusions of these lectures in an article in the *Yale Review* for July, 1913.

Professor DuBois was a hard worker, a clear and logical writer, and his books greatly advanced the interests of sound education in theoretical and applied mechanics. As a teacher, he was most successful, and especially was he insistent that students should acquire a thorough knowledge of fundamental principles. His successor, Professor John C. Tracy, in an obituary notice in the *Yale Alumni Weekly*, wrote as follows:

"A sympathetic interest, a ready wit, and a friendly unconventional manner won his students from the start. He was a clear and original thinker, and a keen but sympathetic critic. Breadth of culture and an unusual power of expression made him a brilliant and inspiring conversationalist. Underneath a quiet and undemonstrative exterior, there was a man chivalrous, sympathetic, always thoughtful of others, loyal, and wholly lovable. Only a few of his closest friends knew how, in his own quiet unostentatious way, he went about doing good, and to them he seemed an almost perfect type of Christian gentleman."

Professor DuBois rarely attended engineering meetings, seeming to feel somewhat awkward outside of the circle of his friends and

* *Transactions*, Am. Soc. C. E., Vol. XVI (1887), p. 191; Vol. XVIII (1888), p. 170.

† *Transactions*, Am. Soc. C. E., Vol. XXVIII (1892), p. 69.

students. In his college days he was a good chess player and a member of the Book and Snake Fraternity, but he took little interest in other social activities. He made six trips to Europe, for rest and relaxation during summer vacations, but he never had a Sabbatical year in whole or in part during his forty years of service as a teacher.

He was married, on June 23d, 1883, to Miss Adeline Blakesley, daughter of Arthur Blakesley, of New Haven, Conn. They had no children, and she survived him only seven months.

Professor DuBois was a member of the American Institute of Mining Engineers, the American Society of Mechanical Engineers, and the Society of Naval Architects and Marine Engineers, as well as several scientific academies and associations.

Augustus Jay DuBois was elected a Junior of the American Society of Civil Engineers on July 7th, 1875, and a Member on October 5th, 1892.

JOHN WALDO ELLIS, M. Am. Soc. C. E.*

DIED OCTOBER 30TH, 1916.

John Waldo Ellis, son of John and Ame Almira Fisher Ellis, was born in Woonsocket, R. I., on September 7th, 1845. He was one of four children, of which three were boys, all noted civil engineers.

Mr. Ellis received his early education at New Hampton Institute, New Hampton, N. H., and at the age of 19 entered the employ of the Boston, Hartford and Erie Railroad, then building from Waterbury, Conn., to Fishkill, N. Y. His advancement was rapid, and he soon became a Division Engineer on the Troy and Greenfield Railroad before the completion of the Hoosac Tunnel. From this road he went to the Norwich and Worcester Railroad then building, and, in 1869, came to Woonsocket, R. I., as Chief Engineer of the Providence and Worcester Railroad, at the same time opening an office for private practice in that place, which he maintained up to within a few years of his death.

Mr. Ellis held the position of Chief Engineer of the Providence and Worcester Railroad, up to the time that road was absorbed by the New York, Providence and Boston Railroad in 1888. Under his direction the road was double-tracked, many branch lines were constructed, the Wilkes-Barre Coal Pier and connection was constructed at Providence, and many bridges, stations, and terminals were rebuilt. During this same period Mr. Ellis' private practice in Woonsocket was at its height, and many prominent engineers of the present day received their first experience in the old Main Street office. The design and direction of the construction of Nourse Mill, of the Social Manufacturing Company, the Alice Mill, of the Woonsocket Rubber Company, and numerous other industrial plants and enlargements in Northern Rhode Island, were a part of the activities of this office.

From 1890 to the time of his death, Mr. Ellis was connected prominently with the various engineering problems of the East. He was Engineer for the Old Colony Railroad Company in the building of the Providence Passenger Terminal, and Engineer Inspector of the Boston and Providence Railroad, from the time of its lease to the Old Colony Railroad, until his death. His connection with various grade crossing matters in Massachusetts and Rhode Island included nearly every important problem that has come up. He was one of the Commissioners for the abolishment of the grade crossings in Lowell, Athol, and Orange, Mass., and was employed as engineering expert by the Cities of Lynn, Worcester, Cambridge, Fall River, Taunton, Haverhill, Readville, and a large number of small towns.

* Memoir prepared by Lester Waldo Tucker, M. Am. Soc. C. E.

As a Water-Works Expert, Mr. Ellis was among the foremost in New England, serving as one of the Commissioners in the valuation of the Newburyport and Gloucester Water-Works when these were taken over by the City. He was also a member of the Commission in the diversion claims against the City of Pittsfield and the claim of the Nassau Paper Company against the Metropolitan Water Board.

As a Town and City Engineer, Mr. Ellis was especially active, serving as Town Engineer of Woonsocket from 1870 to the time it became a city in 1888. He also served as Engineer for the Town of Blackstone, and for other surrounding towns, up to the time of the closing out of his private practice.

As a Hydraulic Engineer, Mr. Ellis was very active, and the Blackstone and other rivers in Massachusetts and Rhode Island have many a dam constructed under his direction. The most prominent of these are the Lonsdale, Ashton, and Wilkinsonville Dams on the Blackstone; the Slatersville Reservoir Dam and Middle Dam on the Branch River, and the Georgiaville Dam on the Woonasquatucket, in Rhode Island.

On March 1st, 1901, Mr. Ellis was elected President of the Providence Gas Company, and took up the active management of that Corporation, holding the position of President and General Manager to the time of his death. Under his direction, this Company became one of the most efficient of the gas companies operating in the East.

Notwithstanding his many engineering engagements and business connections, Mr. Ellis found time to be a most efficient Director and Manager in other fields. He was a member of the Board of Directors of the Industrial Trust Company, of Providence, and Chairman of the Board of the Woonsocket Branch of that Company. He was a Director in the Woonsocket Rubber Company, and many other Corporations. He was also a Trustee of the Woonsocket Institution for Savings, from 1876 to 1908, and a Trustee of the Woonsocket Hospital from its founding, in 1890, to the time of his death. Although a prominent member of many clubs and social organizations, Mr. Ellis had no connection with any fraternal or secret orders. He was a member of the Boston Society of Civil Engineers, serving as President of that Society in 1905. He was also a member of the New England Water Works Association.

His principal diversion in his leisure was that of driving. From the time when he established his home in Woonsocket his stable always contained at least one good blooded trotting horse, and when the roads were good or the sleighing at its best, Mr. Ellis was to be seen among the fastest of those on the speedways. He was a member of the Woonsocket Driving Club, the Roger Williams Driving Club, of Providence, and the Metropolitan Driving Club, of Boston, and it is

interesting to note that only three weeks before his death he drove on the track of the latter Club.

Mr. Ellis was a prominent figure in the political field of Woonsocket for many years. He served as Alderman from his Ward from 1895 to 1897 and was President of the Board during the last two years of this service. In 1904, he was elected State Senator from his city and served on many important Committees.

He was a member of the Board of Trustees of the First Universalist Church for many years.

Mr. Ellis was a man of such marked ability in any of the fields into which he entered that he was recognized as an authority on an unusual range of engineering problems, a public man and a statesman of great ability, and a business man with keen foresight and tremendous energy. The scope of his talents was wide, and indicated a breadth of mentality seldom found in one man.

Mr. Ellis was married on May 23d, 1870, to Mary F. Howe, who, with one son and two daughters, survives him.

He was elected a Member of the American Society of Civil Engineers on July 3d, 1895, and served as a Director from 1904 to 1906, inclusive.

THEODORE NEWEL ELY, M. Am. Soc. C. E.*

DIED OCTOBER 28TH, 1916.

Theodore Newel Ely was born in Watertown, N. Y., on June 23d, 1846. When he retired from the office of Chief of Motive Power of the Pennsylvania Railroad System on July 1st, 1911, he had lived through and participated in the most active period of railroad development that the world has ever seen, having begun his railroad career in 1868.

Mr. Ely was graduated from the Jefferson County (N. Y.) Institute in 1863, and from the Rensselaer Polytechnic Institute, of Troy, N. Y., with the degree of Civil Engineer, in the class of 1866.

After his graduation he had an opportunity to enter the United States Navy, the Navy Department having offered to accept the Institute's examinations as the equivalent of those at Annapolis and grant a full cadetship after a year of sea experience; another offer was that of a Professorship at Rensselaer. He preferred, however, active professional work.

After a brief experience in the office of the City Regulator (City Engineer) of Pittsburgh, Pa., he went to the Fort Pitt Foundry, where he became associated with Gen. Thomas J. Rodman, the inventor of the well-known Rodman gun. The Government specifications for the metal for the guns were very exacting, and Mr. Ely here obtained his first experience in the investigation on a commercial scale of the qualities of metals. After the completion of this work, he was engaged for a short time in coal mining.

In 1868 he entered the Engineer Corps of the Pittsburgh, Fort Wayne and Chicago Railroad, at Pittsburgh. In July of the same year he accepted an offer of the position of Assistant Engineer on the Philadelphia and Erie Railroad, a part of the Pennsylvania Railroad System. In 1869, he was made Superintendent of the Middle Division, with headquarters at Renovo, Pa., and, in 1870, Assistant General Superintendent of the road. Some of the features of Mr. Ely's work during this period were re-alignments of the road, the rebuilding of practically every bridge on the Philadelphia and Erie, and the building of the docks and terminals at Erie Harbor, to take care of the road's prospective combined lake and rail traffic. During this period, also, the first steps were taken in the development of the Pennsylvania Railroad standards of materials and designs, and, in connection with Mr. Frank Thomson, who was Superintendent of the Eastern Division of the Philadelphia and Erie, he designed and made detailed drawings—the first issued at any point on the road—for a standard section of

* Memoir prepared by George L. Fowler, Esq., New York City.

track. A sample mile of this track established its superiority over the previous construction, and, with the exception of the weight of the rail, its general features are still followed. He also conducted, in connection with Mr. William Robinson, an elaborate series of experiments with electric signals, which were fully developed later.

His duties as Assistant General Superintendent of the Philadelphia and Erie included the supervision of the Motive Power Department, of which he took direct charge in 1873, on his appointment as Superintendent of Motive Power.

In 1874, Mr. Ely was made Superintendent of Motive Power of the Pennsylvania Railroad Division, and, in 1882, General Superintendent of Motive Power of all the Lines East of Pittsburgh. His office in both these positions was at Altoona, Pa. Railroad conditions during Mr. Ely's administration at Altoona did not call for a radical change in the types of locomotives or cars, and their development, therefore, was largely in increasing the efficiency of the types then in general use by making important modifications and perfecting their details. He left his imprint on the locomotives of the country by the simple and clean-cut character of the designs developed at Altoona, which eliminated the useless and out-of-place ornamentation which was then a feature of locomotive construction. The same is true with regard to passenger equipment cars, for the improvement of which Mr. Ely's good taste was largely responsible. Among the practices introduced during this period for increasing the efficiency and economy of operations, the following may be briefly mentioned.

At the time of Mr. Ely's appointment as Superintendent of Motive Power, the purchase of materials used was not controlled by specifications of any kind, the brand or reputation of the seller being depended on as a measure of quality. Recognizing that competitive purchasing required as its foundation a clear description of the article to be purchased, Mr. Ely obtained in 1875 permission to establish a Department of Tests, both physical and chemical, to develop the necessary specifications for the materials to be bought, and to examine the materials received to insure that they met the requirements of the specifications. Mr. Ely wisely selected young and ambitious men as the heads of the two branches of the Test Department, one being John W. Cloud and the other the late Charles B. Dudley, M. Am. Soc. C. E., and his firm support of his subordinates was largely responsible for the success of the new plan, as purchasing on the basis of specifications and tests alone naturally aroused strong opposition from many manufacturers, particularly those with established brands. In some cases, however, the manufacturers themselves were the strongest advocates of the general use of the specifications. The new Department speedily developed great value in the investigation of many of the technical questions which were constantly arising in railroad work, and it has made

notable contributions in the line of scientific investigations covering a wide range of subjects.

Realizing the increasing responsibilities of the Mechanical Department, Mr. Ely encouraged the entrance into the service of young men of technical education, who were given a course of practical training in the shops under the same rules and regulations as the regular apprentices, their subsequent advancement depending on their development of the necessary qualifications.

The piecework system, which is now used on the whole Pennsylvania System, was introduced during the early part of Mr. Ely's administration. Another feature was the extensive use of committees for the study of important questions.

Mr. Ely's encouragement and the assistance given by his organization were large factors in the introduction and successful development of the automatic car coupler, the air brake, and other features of modern railroad practice.

An important undertaking was the establishment at Altoona, in 1889, of the Juniata Shops for building locomotives. These shops have been extended from time to time since to keep pace with the increasing size of modern locomotives, and still build the greater number of locomotives required by the Company.

Another notable practice established under Mr. Ely's direction was the pooling of the freight cars of all the lines of the Pennsylvania Railroad System, so far as repairs were concerned.

Incidents of this period were the active part which Mr. Ely took in the rebuilding of the road at Johnstown, after the flood in 1889; his work as a member of the Commission on Safe and Vault Construction, appointed by Act of Congress in 1890, for the purpose of improving the vault facilities of the Treasury Department; the exhibits of the Pennsylvania Railroad Company at the various International Expositions—the Centennial, Philadelphia, 1876; Paris, 1889; Columbian, Chicago, 1893; as well as the later ones, Louisiana Purchase, St. Louis, 1904; and Jamestown, 1907—which were prepared and carried out under his direction.

In 1893, Mr. Ely was appointed Chief of Motive Power of the Pennsylvania Railroad Lines East and West of Pittsburgh, with office at Philadelphia. Although in this position his duties were supervisory, he kept in close touch with the work of development of locomotives and passenger and freight cars to meet the changing conditions, both as to traffic and as to materials for car construction. He gave close study to and took an active part in the consideration of the questions of policy involved in the increases in the capacities of locomotives and cars, especially in freight service; the substitution of steel for wood in the construction of both freight and passenger cars; and the establishment of the general principles of the designs.

Other activities during this period were his work as Chairman of the Rail Committee of the System, charged with the improvement of the rail used; as a member of various committees of the American Railway Association; as a member of the Permanent Commission of the International Railway Congress; as President of the Eastern Railroad Association, dealing with patent matters; as a Trustee of the Philadelphia Commercial Museum, which is devoted to the development of the foreign trade of the United States; and as a member of the Pennsylvania State Commission on the Chestnut Tree Blight. He was also a Director, in the interest of the Pennsylvania Railroad, of the Pennsylvania and Cambria Steel Companies.

Mr. Ely was a member of the Institution of Civil Engineers of Great Britain, the American Society of Mechanical Engineers, the American Institute of Mining Engineers, and an Honorary Member of the American Institute of Architects.

He was also deeply interested in science and art, and took an active part in many organizations for their advancement, among them being the American Society for the Advancement of Science, the American Philosophical Society, the Franklin Institute, the Drexel Institute, the American Academy in Rome, Italy, of which he was Vice-President, and the Philadelphia Orchestra Association, of which he was a Trustee.

Although ill health led to his retirement from active service with the Pennsylvania Railroad in 1911, it did not entirely deprive him of participation in the many affairs of life of which he was a part. His keen analytical and judicial mind, trained and broadened by his studies and an experience covering almost the entire period of railroad development, made him a valued adviser in all the activities with which he came in contact.

Mr. Ely held the degree of Civil Engineer from Rensselaer Polytechnic Institute, as a graduate, and had conferred on him the honorary degrees of Master of Arts, Yale, 1897, and Doctor of Science, Hamilton College, 1904.

Among the social organizations with which he was identified were the Philadelphia and the Merion Cricket Clubs, of Philadelphia; the University, Century, and Engineers Clubs, of New York City; and the Metropolitan Club of Washington, D. C.; the New England Society of Pennsylvania, and the Sons of the American Revolution.

Mr. Ely is survived by his four children—Mrs. Charles L. Tiffany, of New York City, the Misses Gertrude and Henrietta Ely, of Bryn Mawr, Pa., and Carl B. Ely, Assoc. M. Am. Soc. C. E., Superintendent of the Bridge Department of the Bethlehem Steel Company, Steelton, Pa.

Mr. Ely was elected a Member of the American Society of Civil Engineers on March 2d, 1881, and served as a Director in 1892-93.

RICHARD EVANS, M. Am. Soc. C. E.*

DIED DECEMBER 30TH, 1916.

Richard Evans was born at Caracas, Venezuela, on November 15th, 1855, and, on his father's side, came from the Evans family long established in New England. While he was quite young, his parents removed to the United States and settled in Woodbury, N. J. Here he received his preliminary education before entering the Polytechnic College of Pennsylvania, from which he was graduated with the Class of 1875.

In 1876, Mr. Evans was employed as Rodman and Levelman on the location of the Philadelphia and Atlantic City Railroad, and, from 1877 to 1879, he was engaged as Levelman and Transitman on topography and revision of lines and grades in the Twenty-third Ward for the City of Philadelphia. In 1879, he was appointed Transitman, and, later, Assistant Engineer on the preliminary and location surveys for the Danville and Shamokin Railroad, in Pennsylvania, and, in 1880, he was made Assistant Engineer on the location of the Five Mile Beach Railroad and laying out the Town of Anglesea, N. J. From July, 1880, to February, 1881, he served as Transitman in the Maintenance of Way Department of the Pennsylvania Railroad.

In 1881, Mr. Evans went to Mexico as Transitman and Chief of Field Party on the location surveys for the Mexican National Railroad, returning in 1882, to become Assistant Engineer on the New River Branch of the Norfolk and Western Railroad. In 1883, he was appointed Assistant Engineer with the Pennsylvania Schuylkill Valley Railroad Company, on the revision of part of its line. He designed and made the plans for arch culverts, piers, and bridge abutments on 6 miles of heavy construction, including the Schuylkill River crossing and viaduct approach.

From 1884 to 1887, Mr. Evans was engaged with the Survey Department of the City of Philadelphia on sewer construction in the Manayunk District and on laying out new streets in the Twenty-second Ward.

In 1887, Mr. Evans went West and was employed as Assistant Engineer with the St. Louis and San Francisco Railroad Company. Returning to the East in 1888, he was engaged until 1890 in private practice, making plans, estimates, and superintending the construction of macadamized and telford roads, highway bridges, etc., in Montgomery County, Pennsylvania. Afterward, he accepted for a short time a position as Principal Assistant Engineer on the Philadelphia and Seashore Railroad.

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

In July, 1890, Mr. Evans established himself in private practice at Hagerstown, Md., in partnership with Mr. C. C. Vandevanter, which was continued until 1893. He then removed to Jamaica, N. Y., where he formed a partnership with his brother, Mr. C. A. Evans, and continued in private practice as a Consulting Engineer until his death, which occurred on December 30th, 1916. He was married in Philadelphia, Pa., about 1887, but his wife died two years later.

In his work and conduct, which was always above criticism, Mr. Evans exemplified the best influences of his profession. Realizing his incompatibility with the prevailing requirements of corporation service as he saw them, he preferred the private practice of engineering for which he felt himself better fitted temperamentally. Holding to that which he considered to be right, his decisions in regard to his work were made regardless of who was or was not benefited thereby. In the study of any contemplated project, he always showed that calmness, ease, and continuity of application which distinguish the trained engineer.

Mr. Evans was elected a Member of the American Society of Civil Engineers on June 7th, 1893.

FRANK FIRMSTONE, M. Am. Soc. C. E.*

DIED JUNE 27TH, 1917.

Frank Firmstone, the son of William and Mary Elizabeth Firmstone, was born on August 29th, 1846, at the Glendon Iron Works, near Easton, Pa., which his father had built in 1842. He received his early education at the Old Philips School in Easton. Later, he was sent to the Saunders Military Institute, in Philadelphia, Pa., where he was prepared for the Polytechnic College of Pennsylvania, and was graduated from that college as a Mining Engineer in June, 1865.

In November, 1865, Mr. Firmstone was employed as Levelman on surveys for the Wilmington and Brandywine Railroad, which position he held until March, 1866.

In January, 1867, he became associated with his father, as Assistant Superintendent, in the management of the Glendon Iron Works, remaining in this position until May, 1877, when his father died. Mr. Firmstone then took full charge of the Iron Works as General Manager, and retained this position until 1887, when he retired from active business. As Assistant Superintendent and as General Manager he made the designs and superintended the construction of all new work at the plant, including blast furnaces, etc., as well as repairs and alterations.

Subsequent to 1887, he became associated with the Cranberry Iron and Coal Company, serving for a number of years as its President and as a Director on the Boards of all its subsidiary companies until his death, which occurred at his home in Glendon, Pa., on June 27th, 1917.

He is survived by his brother, Mr. Harry Firmstone, of Longdale, Va.

Among other societies and clubs Mr. Firmstone was a member of the American Institute of Mining Engineers, and as such had contributed to its publications many interesting and valuable papers on blast furnace practice and on matters pertaining to the manufacture of pig iron, on which subject he was considered quite an authority.

He was also a member of the American Society for Testing Materials, American Forestry Association, Engineers' Club of New York City, Automobile Club of Philadelphia, Pa., Country Club of Northampton County, Pomfret Club of Easton, Pa., Northampton County Historical and Genealogical Society, and Trinity Protestant (Episcopal) Church, of Easton, Pa.

Mr. Firmstone was elected a Member of the American Society of Civil Engineers on August 7th, 1878.

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

JAMES WALTER GRIMSHAW, M. Am. Soc. C. E.*

DIED FEBRUARY 15TH, 1917.

James Walter Grimshaw was born at Manchester, England, on April 19th, 1852. In 1868, he was sent to Germany where he was a pupil of Carl Bach, a well-known civil engineer of Stuttgart, until 1870. He then entered the machine shops of E. Harn, of the same city, where he served an apprenticeship of one year. In 1871, Mr. Grimshaw entered the Stuttgart Royal Polytechnic School, from which he was graduated in Civil Engineering in 1874.

After his graduation, Mr. Grimshaw returned to England, where he was employed until 1877 in the Engineering Departments of Messrs. Sharp, Stewart and Company and Messrs. Ormerod, Grierson and Company, of Manchester. He was also engaged for a short time as Resident Engineer of the Netham Chemical Works at Bristol.

In 1877, Mr. Grimshaw went to Australia where he spent the greater part of his professional life. He first entered the service of the South Australian Government and received the appointment of Resident Engineer in the Harbors and Jetties Department, where he remained until 1880. He then entered the service of the Government of New South Wales, in the Rivers and Harbors Department, his first position being Resident Engineer of the Sydney Water Supply Works, in charge of the construction and maintenance of the canals, tunnels, aqueducts, etc.

About 1890, Mr. Grimshaw made the surveys for the proposed water supply for the City of Armidale, and supervised the completion and testing of the steel service reservoir for the Albury water supply.

On the completion of this work, he was appointed Resident Engineer on the Richmond River and Harbor Works, where two breakwaters and a training wall were being constructed. Subsequently, he was sent to Sydney as Resident Engineer over the works in Sydney Harbor and the South Coast District. In this position he had charge of extensive wharf construction and the conversion of Darling Island into a deep-water shipping depot.

In 1901, Mr. Grimshaw retired from the service of the Government of New South Wales and returned to England, where he resided until his death which occurred at Brighton, on February 15th, 1917.

He was a member of St. Stephen's Club, of London, and of the Institution of Civil Engineers of Great Britain.

Mr. Grimshaw was elected a Member of the American Society of Civil Engineers on November 7th, 1888.

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

WILLIAM OSWALD HENDERER, M. Am. Soc. C. E.*

DIED FEBRUARY 8TH, 1917.

William Oswald Henderer, the son of Myers Henderer and Euretta Curtis Henderer, was born on May 11th, 1865, in Greenbush, now known as Rensselaer, Rensselaer County, N. Y. He received his early education in the district schools of Schodack Landing and Castleton, in Rensselaer County, and in the grammar and high schools of Albany, N. Y. His technical training was received at Rensselaer Polytechnic Institute, Troy, N. Y., where he was a member of the Class of 1887.

From June, 1887, to January, 1888, Mr. Henderer served as an Assistant in the office of the City Engineer, of Troy. During the spring and summer of 1888 he worked on a preliminary survey through Northern Ohio for the Pennsylvania Railroad Company.

From May, 1888, until April, 1891, he was with G. W. G. Ferris and Company, of Pittsburgh, Pa., as Shop Inspector on bridge, railroad, and viaduct steelwork, and it was here that he became acquainted with Frank C. Osborn, M. Am. Soc. C. E., with whom, later, he was associated.

From April to November, 1891, Mr. Henderer was Draftsman and Assistant Engineer for the Detroit Bridge and Iron Works, and from November, 1891, to March, 1893, he served in a similar capacity with the Berlin Iron Bridge Company, of East Berlin, Conn.

In March, 1893, he went to Cleveland, Ohio, to be with Mr. Osborn, in charge of inspection and tests. From December, 1897, to June, 1900, as a member of the Osborn Company, Civil Engineers, he was in charge of structural design, inspection, and general office work. During this period, the Brooklyn-Brighton Viaduct and the South Rocky River Viaduct, in Cuyahoga County, Ohio, and the Zanesville Y-Bridge, in Zanesville, Ohio, were among the larger and more interesting works handled by the Company.

In June, 1900, The Osborn Engineering Company was incorporated, and Mr. Henderer became its first Vice-President. This position he held until the summer of 1910, at which time Mr. Osborn retired from active charge of the company, and Mr. Henderer became President.

In recent years, the Boston, New York, Cleveland, Washington, and Detroit baseball parks, and the factory buildings for the Firestone Tire and Rubber Company and The B. F. Goodrich Company, have been included among the more important structures designed by the Company.

* Memoir prepared by Kenneth H. Osborn, Assoc. M. Am. Soc. C. E.

Mr. Henderer continued as President of the Company until his death, on February 8th, 1917, at Miami, Fla. He had been absent from Cleveland only about 10 days on a fishing trip, when he was seized by a sudden attack of peritonitis. He was taken to a hospital in Miami, but lived only a few days after the attack.

Mr. Henderer was married on June 21st, 1893, to Ida F. Mayer, of Cleveland, and had one daughter, Geraldine.

He was an active member of the Cleveland Engineering Society, and had served as President of that organization. He was also a member of the American Society for the Promotion of Engineering Education, the Cleveland Athletic Club, the Shaker Heights Country Club, and the Chippewa Lake Club. He was deeply interested in the Masonic organizations of Cleveland, and was very active in all those of which he was a member.

Mr. Henderer was elected a Member of the American Society of Civil Engineers on April 3d, 1901.

ARTHUR HIDER, M. Am. Soc. C. E.*

DIED JULY 28TH, 1916.

Arthur Hider was born in London, England, on February 29th, 1844, and died at his home in Greenville, Miss., on July 28th, 1916. He was the son of James and Maria (Dear) Hider. In 1853, when he was nine years of age, his family moved from England to London, Ont., Canada. He received his early education in the schools of the latter place and afterward taught school there for a while. In 1864, at the age of twenty, he went to Cleveland, Ohio, where he began the study of engineering, as a private pupil, under Peter Emslie, a civil engineer, with whom he spent about one year.

In 1866, Mr. Hider was employed as a Draftsman by George Steuly, City Engineer of Louisville, Ky., and, after one year's service in that position, was appointed Assistant City Engineer and given charge of the public works in one-half of the city. After the death of Mr. Steuly, in 1869, Mr. Hider was continued in the same position under the late I. M. St. John, M. Am. Soc. C. E., who succeeded Mr. Steuly as City Engineer, until 1871, when the late Thomas P. Shanks, M. Am. Soc. C. E., became City Engineer. Mr. Hider was then appointed Principal Assistant City Engineer, and given charge of all improvements made by the city, except in the Sewer Department. He continued to serve in this position until some time in 1876, when Mr. Shanks was retired from office, and he, as the Principal Assistant, along with him.

From 1876 to the early part of 1879, Mr. Hider was engaged with his former Chief, Mr. Shanks, in engineering and contracting work, during which time they constructed a reservoir at Anchorage, Ky., and, for about one year, were engaged on masonry work at the new reservoir at Louisville, Ky., both of which were under the supervision of the late Charles Hermany, Past-President, Am. Soc. C. E., Chief Engineer of the Louisville Water-Works.

Mr. Hider entered the Government service in 1879, and, for a short time, was employed under Charles R. Suter, M. Am. Soc. C. E., Major, Corps of Engineers, U. S. Army (now Brigadier-General, *Retired*), in making hydrographic surveys and physical observations on the Mississippi River, near Arkansas City, Ark. Maj. Suter was appointed a member of the Mississippi River Commission, which body was created by Act of Congress, dated June 28th, 1879, and Mr. Hider was assigned to duty under Lieut. Smith S. Leach, Corps of Engineers, the Secretary of that Commission. From October, 1879, to November, 1880, he was engaged in making hydrographic surveys and collecting physical data on the river near Lake Providence, La., and, later, had charge of

* Memoir prepared by Charles H. West, M. Am. Soc. C. E.

a party taking slope observations along the river between Cairo, Ill., and New Orleans, La.

The Commission was now ready to begin construction, and, in September, 1881, Mr. Hider was assigned to duty as one of the Assistant Engineers in the Third Mississippi River District, extending from the White River to a few miles below the mouth of the Yazoo River. The Engineer Officer in charge of the district was Lieut. W. L. Marshall, who, later, became Chief of Engineers, U. S. Army. During the few years that Mr. Hider served under this officer, they learned to regard each other highly, and there ever after existed a friendly feeling between them.

At the time when Mr. Hider entered the Government service under the Mississippi River Commission, very few reliable data were available as to the regimen of the Mississippi, and few, if any, precedents of practical value as guides in a project of such character and magnitude as that which had been assigned to the Commission. His first service was in connection with surveys and observations to collect data necessary for a study and development of plans for the improvement of the river, but when it was decided to begin construction, he was transferred to that work, and soon became the Principal Assistant Engineer in charge of all revetment and other work of channel improvement in the Third Mississippi River District, serving continuously in that position until his death.

The first works of construction were necessarily experimental in type, as were also the various kinds of plant needed for carrying on the work. Mr. Hider was intimately connected with each step in the development of suitable types of construction, and also had much to do with the design and construction of towboats, hydraulic graders, and the various other items of plant required for the work in the Third District. He took great interest in the development of plans for the improvement and control of the river, and no small share of credit for successful work is due to his faithful, untiring, and patient attention to the duties of his position. He came to be regarded as an authority on bank revetment and other channel works, and his counsel in such matters always had weight.

Mr. Hider was connected with levee construction only in a limited way, but he was a close observer of what was going on in that line, and had very clear views in regard to that work.

In addition to his work under the Mississippi River Commission, he, occasionally, while on leave of absence and during spare time, served as Consulting Engineer in connection with municipal improvements, some of which were the design and construction of water-works systems at Greenville, Miss., Lake Providence, La., and other places; he was expert member of the Committee to determine the value of the water-works system of Memphis, Tenn., when that system was taken over by the City of Memphis.

Mr. Hider enjoyed remarkably good health until the last three years of his life. During the spring of 1913, while temporarily in charge of the work of closing the crevasse in the levee near Beulah, Miss., he was exposed to very inclement weather, with the result that he was taken seriously ill and never after entirely regained his health. He was unable to attend to active duties for more than a year prior to his death, but he continued to go to the office and, except during the last few weeks, he could be found at his desk every day when he was strong enough to leave home.

Mr. Hider was indeed a veteran of the Engineer Service of the Mississippi River. There being no provision in law for the retirement of civilian engineers in the service of the Government, he, like many others, remained on duty until advanced in age and literally worn out.

He lived to see nearly all the Engineer Officers under whom he had served in the early days on the river retired with high rank, and, as these men were near his own age and counted among his friends, he was always pleased to hear of any good fortune that came to any of them.

In later times, it was his province to serve under District Officers who were many years younger than himself, and to each of these he gave loyal assistance. They, in turn, recognized his ability and ripe experience, and his candid manner and earnest attention to duty never failed to win their confidence and esteem.

He was a good organizer, and believed in strict discipline. He recognized authority in those above him, and demanded obedience to orders from those under him. He was highly respected by his subordinates, and, though they dreaded his displeasure, they delighted in his approval, for he was just in his dealings with them and ever ready to give credit where it was due. It was a pleasure to him to advise and otherwise help along young engineers who appeared to be earnest and appreciative of his guidance.

Mr. Hider took an active interest in the civic affairs of the community in which he lived. There was no pretense and very little diplomacy in his nature, and he was outspoken in his opinions. He was well informed on many subjects other than his profession, and had a fine appreciation of music and art.

Mr. Hider was a member of the Protestant Episcopal Church, and though not outwardly a devout churchman, he had deep religious convictions. He loved the quietude of his home life, and was a devoted husband and kind father, and although he seemingly cared but little for social life in general, he was fond of the companionship of his friends.

He was married in Louisville, Ky., on October 6th, 1873, to Emma K. Anderson, who, with two daughters and three sons, survives him.

Mr. Hider was elected a Member of the American Society of Civil Engineers on September 7th, 1881.

SIDNEY WILLETT HOAG, Jr., M. Am. Soc. C. E.*

DIED NOVEMBER 1ST, 1916.

Sidney Willett Hoag, Jr., son of Sidney Willett and Ann Augusta Hoag, was born in New York City, on June 5th, 1857. He received his preliminary education in the public schools and was admitted to the College of the City of New York in 1872 as a student in the scientific course, from which he was graduated in June, 1877. From 1877 to 1879, he pursued the post-graduate course in Civil Engineering in the same college under the late Professor A. G. Compton, Assoc. Am. Soc. C. E., and was graduated with the certificate of Civil Engineer.

In 1879, after leaving college, Mr. Hoag went with the New York City and Northern Railroad, being first engaged on trestle construction. Subsequently, during construction, he had charge of the distribution of materials and supplies, and later was engaged in the construction of roadbed, turn-tables, and depots, from Croton Lake to Lake Mahopac.

In 1880 he entered the service of the City of New York, being engaged in the Department of Public Parks as an Assistant Engineer. His efforts in the Park Department were directed toward the public improvement of the annexed district. He had charge of various classes of engineering work under the jurisdiction of the Park Department, including surveys, laying out of streets, monumenting, preparation of tax maps, rule, damage, and benefit maps, and work of general construction involving regulating and grading, and, in addition, he directed the work of the various field parties.

In 1891, Mr. Hoag was appointed an Assistant Engineer in the Department of Docks and Ferries, and was assigned by George S. Greene, Jr., M. Am. Soc. C. E., then Engineer in Chief, as head of the drafting-room. In this position, Mr. Hoag directed the preparation of plans and specifications for various works of construction, undertaken by the Department along the water-front, such as piers, bulkheads, freight sheds, and freight and passenger terminals, and the approval of structural features of all plans submitted by private owners and lessees for all kinds of wharf structures.

In 1908, Mr. Hoag was appointed Deputy Chief Engineer of the Department under Charles W. Staniford, M. Am. Soc. C. E., Chief Engineer. During his incumbency as Deputy Chief Engineer, the Department of Docks carried out many important works of construction, involving piers, bulkhead walls, freight sheds, and ferry terminals. Some notable pieces of construction on which Mr. Hoag was engaged are the municipal ferry terminal at St. George, Staten Island, the municipal ferry buildings at the Battery, known as the Manhattan

* Memoir prepared by Charles W. Staniford, M. Am. Soc. C. E.

Terminal of the South Brooklyn Ferry, the Whitehall Terminal of the Staten Island Ferry, and also the viaduct approach to the St. George Ferry, at St. George. The most conspicuous and important undertaking by the Department of Docks during this period was the construction of the great transatlantic steamship terminal popularly termed the Chelsea Section. This is on the North River water-front, and covers the section from West 14th to West 23d Streets. It involved the construction of nine piers, with freight sheds thereon, and putting in heat, light, and power equipment for operating purposes. This section represents an expenditure of many millions of dollars, and the accommodation it affords for large transatlantic liners is not equalled anywhere in the world.

This large undertaking by the Department involved an enormous amount of detail work in connection with the preparation of plans and specifications, and the examination and approval of plans submitted by contractors during construction.

The successful completion of the Chelsea Section demonstrated Mr. Hoag's capacity for hard work, and his great attention to detail enabled the Department to carry out successfully many large undertakings involving extreme detail in steel construction and intricate problems in connection with heat, light, and power equipment. Mr. Hoag was a loyal assistant, conscientious in everything he did, and, above all, a man of sturdy integrity. His work was his hobby.

He never had any interest outside of his professional work, and was held in high esteem by the fellow members of his Profession.

In March, 1904, he became a member of the Society of Municipal Engineers of the City of New York, and at once took an active interest in its affairs. He was rewarded with honors for his labors, being elected Second Vice-President in 1910; First Vice-President in 1911, and President of the Society in 1912. He continued his interest in the Society, being on the Board of Directors as Past-President, at the time of his death.

In 1905, Mr. Hoag delivered, before the Municipal Engineers, a very interesting paper entitled "The Dock Department and the New York Docks." The paper dealt with the history of the Dock Department and its work, and contained considerable detailed data relative to water-front construction. It had a wide distribution, and was considered the most meritorious paper of the year. For this Mr. Hoag received the Society medal in recognition of his achievement.

In 1914, his health failed, and he was compelled by his physical condition to give up active work. He retired from the Department of Docks on a pension after 35 years in the service of the City.

After about a year's rest, he regained some of his strength and joined B. F. Cresson, Jr., M. Am. Soc. C. E., assisting the latter in the preparation of plans and specifications for the construction of

an extensive water-front and railroad terminal development at Bayonne, N. J. He was associated with Mr. Cresson up to the time of his death.

System, the love of detail, and the habit of accumulating interesting data pertaining to his Profession, were some of Mr. Hoag's personal characteristics. He was a thorough, painstaking, and conscientious worker, and the bigger the job, the happier it made him. Although, in his younger days, he was fond of athletics and had joined the New York Athletic Club, engaging in running races, his whole time, during his later years, was given to the work of his Profession. He was a capable executive, had a frank, genial personality, a high code of honor, and won the admiration of those who knew him.

Mr. Hoag was a member of the New York Athletic Club, the Municipal Engineers of the City of New York, and the Royal Arcanum.

Mr. Hoag was elected a Member of the American Society of Civil Engineers on September 2d, 1885. He served as a member of the Nominating Committee in 1913-14.

CHARLES WILCOX HOTCHKISS, M. Am. Soc. C. E.*

DIED OCTOBER 28TH, 1916.

Charles Wilcox Hotchkiss, the son of Edgar F. and Caroline Enos Hotchkiss, was born at Unadilla Forks, N. Y., on June 19th, 1863.

Mr. Hotchkiss began his engineering career as a Rodman on the New York, West Shore, and Buffalo Railroad, when he was 20 years old. He left that position after a short time to enter the employ of the Pennsylvania Railroad Company as Rodman and Assistant Engineer, which position he retained until August, 1886, when he went to the Michigan Central Railroad, as Assistant Engineer in charge of construction. In 1890, he was appointed Division Engineer in charge of the Chicago Division, and, in May, 1895, he became Chief Engineer of the Chicago, Hammond, and Western Railroad, in full charge of all matters in connection with its construction. In 1897, Mr. Hotchkiss held the position of Chief Engineer and Superintendent of Construction for the Chicago, Hammond, and Western Railroad Company, and of the Michigan Central Terminal Railroads, in charge of the extension of the Chicago Terminal. In 1899, he was appointed Chief Engineer of the Chicago Transfer and Clearing Company, and Consulting Engineer of the Michigan Central System.

In 1900, Mr. Hotchkiss became President of the Indiana Harbor Railroad Company, and constructed the Indiana Harbor Belt Railroad from Indiana Harbor around Chicago, as well as the Chicago, Indiana and Southern Railroad, from Chicago to Danville, Ill. After completing these roads in 1905, he effected their consolidation with the New York Central System, and became General Manager of the consolidated companies.

In 1912, Mr. Hotchkiss became President of the Chicago Utilities Company and the Chicago Tunnel Company, and, in 1913, he was called to New York City to take over the management of the various properties and interests of the late H. H. Rogers. At the time of his death, which occurred at Battle Creek, Mich., on October 28th, 1916, from organic heart trouble, he was Chairman of the Board of Directors of the Virginian Railway Company; Chairman of the Atlantic Coast Electric Railway Company; President of the Chicago Tunnel Company, the Rail Joint Company, the Richmond Light and Railroad Company, the Staten Island Midland Railway Company, and of various other power, light, and railroad companies.

Mr. Hotchkiss was a pioneer in the promotion and development of the Calumet Manufacturing District of Indiana, particularly in the Cities of East Chicago, Indiana Harbor, Hammond, and Michigan

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

City. By his construction and development of the railroad facilities of that District he laid the groundwork for, and made possible, the present tremendous growth of these localities. He retained an active interest in the Calumet District until his death, and the recently completed building for the First Calumet Trust and Savings Bank, at East Chicago, which is the finest bank building in Northern Indiana and was erected under the personal direction of Mr. Hotchkiss, together with the Indiana Harbor Belt Railroad, are the two outstanding monuments to his activities in that region. He also had large real estate holdings there, extending from Laporte and Michigan City, Ind., to Chicago, Ill.

Mr. Hotchkiss is survived by his widow, Mrs. Mary Jayne Hotchkiss, and by two brothers and one sister.

He was a member of the Chicago, Mid Day, Press and Engineers' Clubs, and of the Indiana Society, of Chicago, Ill.; Duquesne Club, of Pittsburgh, Pa.; the Lawyers', Engineers', Transportation, and Richmond County Country Clubs, of New York City; the Western Society of Engineers; the American Railway Engineering Association; and a Life Member of the Art Institute of Chicago. He was also a member of the Protestant Episcopal Church and the Medinah Temple Shrine.

Mr. Hotchkiss was elected a Member of the American Society of Civil Engineers on January 5th, 1898.

WILLIAM HENRY HUNTER, M. Am. Soc. C. E.*

DIED FEBRUARY 27TH, 1917.

William Henry Hunter, the son of Henry Hunter, was born at Cork, Ireland, on June 16th, 1849. While he was quite young, his parents removed to England, and the boy was educated at private schools at his home in Sunderland and at the College of Physical Science, University of Durham, at Newcastle-on-Tyne.

In 1866, he entered the Engineering Workshops of the River Wear Commissioners where he remained until 1868, when he went into the office of the late Thomas Meik as a pupil.

Having served his pupilage, Mr. Hunter, in January, 1870, was employed as Assistant in the office of Messrs. Meik and Nisbet, Harbor and Dock Engineers, of Edinburgh and Sunderland, and was engaged on harbor and dock work on the Rivers Wear, Blyth, and Coquet, at Burntisland and Ayr, and also on surveys for the Hylton, Southwick, and Monkwearmouth Railway, a branch of the North Eastern Railway.

From January, 1872, to September, 1873, he served as Resident Engineer on the construction of the Hylton, Southwick, and Monkwearmouth Railway in the County of Durham. He then accepted the position of Assistant Engineer on the reconstruction of the River Weaver Navigation, in the County of Chester, and remained in that position until 1882. The work consisted of enlarging and adapting the River Weaver for navigation by large barges and coasting vessels, thus giving commercial outlet to the interests engaged in the Cheshire salt trade.

From 1882 to 1885, Mr. Hunter was engaged as Chief Assistant to the late Sir Edward Leader Williams, on the surveys, preparation of designs, and Parliamentary contests, in connection with the project to connect the City of Manchester with the sea by a ship canal, and on work for the regulation and improvement of the River Dee in Cheshire and North Wales.

In 1885, when the Manchester Ship Canal Company was incorporated, Mr. Hunter was appointed Assistant Chief Engineer, and, as such, was directly and responsibly concerned with all the engineering operations connected with the actual design and construction of that waterway, including the Canal proper and all its auxiliary works.

In 1895, he was made Engineer and, in 1896, Chief Engineer of the Manchester Ship Canal, which position he held until 1910. During this time Mr. Hunter had charge of the maintenance of the entire project and carried out all additional works necessary to its development, including the extension of the great system of docks, railways,

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

etc. It was during his incumbency as Chief Engineer, that the new Dock No. 9 was opened, with great ceremony, by His Majesty, the late King Edward VII, on July 5th, 1905.

In 1910, Mr. Hunter was appointed Consulting Engineer of the Manchester Ship Canal, which position he held until his death, which occurred at his home at Bank House, Woodley, Cheshire, on February 27th, 1917.

Mr. Hunter was recognized as the foremost English authority on canal and harbor construction, equipment, and operation. In 1898, he was appointed a member of the Comité Technique which was constituted by the French Government to consider and prepare plans, for the New Panama Canal Company, for the French Panama Canal, and, in 1905, at the request of the United States Government, he became a member of the Advisory Board of Consulting Engineers, appointed by the President to consider and report on the plans for the American Panama Canal project, for which he strongly favored a sea-level, as against a lock, canal.

Mr. Hunter was a member of the Institution of Civil Engineers and frequently took part in the discussion of papers on canals and waterworks. He also presented a paper on the "Artificial Waterways in Great Britain",* before the International Engineering Congress, held in St. Louis, Mo., in 1904, under the auspices of the Society.

He was also a member of the Society of Arts and the Manchester Association of Engineers, and a Commissioner for the Navigation for the Upper Mersey. Mr. Hunter was of a deeply religious nature and was a devoted member of the Plymouth Brethren, frequently preaching and taking an active part in their meetings in Lancashire and Cheshire. A strenuous business man, he was noted for his gentleness and courtesy as husband, father, and host, and his love for children and their love for him was a frequent cause of remark. He is survived by his widow and three children.

Mr. Hunter was elected a Member of the American Society of Civil Engineers on February 7th, 1906.

---

* *Transactions*, Am. Soc. C. E., Vol. LIV, Part F, p. 183.

JAMES EDGAR JENKINS, M. Am. Soc. C. E.*

DIED JULY 5TH, 1917.

James Edgar Jenkins was born in Vernon, N. Y., on November 25th, 1878. He received his early education in the Vernon schools, and was graduated from the village High School in 1896.

His father, Josiah W. Jenkins, is a well-known surveyor and hydraulic engineer, and from him the boy learned the rudiments of engineering so well that he qualified as Rodman with the United States Deep Waterways Survey, on which work he was engaged during 1897-98.

In 1898, the Utica Gas and Electric Company undertook the hydro-electric development of West Canada Creek, at Trenton Falls, N. Y., and, for nearly three years, Mr. Jenkins was Instrumentman and Inspector on this project.

In the mid-term of 1900, he entered Rensselaer Polytechnic Institute where he quickly overtook his class, and was graduated in excellent standing with the degree of C. E. in 1904. During his summer vacations he was employed as Instrumentman on the Rutland Canadian Railroad and the Fort Plain, N. Y., Water-Works.

Immediately after his graduation, Mr. Jenkins entered the employ of the engineers in charge of the Pennsylvania Railroad Tunnels, in New York City, as Rodman, and shortly became Chief of Alignment on the East River Division. This led to a position as Engineer with the Naughton Company and Arthur McMullen, on Sections A and B.

For the next three years he was Engineer for the Thomas Crimmins Contracting Company, on Barge Canal Contract No. 9 and on several minor contracts in New York City.

Mr. Jenkins was then employed as Engineer for Smith, Hauser, Locher and Company, on Aqueduct Contract No. 66, which position he retained for nearly three years. While engaged on this work his health began to fail, due to pulmonary trouble, and he sought to regain it by a stay at Southern Pines, N. C. This sojourn was shortened, in order that he might undertake the alterations of the dam, spillways, etc., of the Union Manufacturing and Power Company, on Broad River, South Carolina.

Shortly thereafter, in March, 1915, Mr. Jenkins became Superintendent for the Cook Construction Company, on Contract No. 2 of the Montreal Aqueduct Enlargement. When this work was closed down by war conditions, he returned to New York and, after a brief rest, took charge of the erection of a large concrete chemical mill at

* Memoir prepared by H. R. Beebe, Assoc. M. Am. Soc. C. E.

etc. It was during his incumbency as Chief Engineer, that the new Dock No. 9 was opened, with great ceremony, by His Majesty, the late King Edward VII, on July 5th, 1905.

In 1910, Mr. Hunter was appointed Consulting Engineer of the Manchester Ship Canal, which position he held until his death, which occurred at his home at Bank House, Woodley, Cheshire, on February 27th, 1917.

Mr. Hunter was recognized as the foremost English authority on canal and harbor construction, equipment, and operation. In 1898, he was appointed a member of the Comité Technique which was constituted by the French Government to consider and prepare plans, for the New Panama Canal Company, for the French Panama Canal, and, in 1905, at the request of the United States Government, he became a member of the Advisory Board of Consulting Engineers, appointed by the President to consider and report on the plans for the American Panama Canal project, for which he strongly favored a sea-level, as against a lock, canal.

Mr. Hunter was a member of the Institution of Civil Engineers and frequently took part in the discussion of papers on canals and waterworks. He also presented a paper on the "Artificial Waterways in Great Britain",* before the International Engineering Congress, held in St. Louis, Mo., in 1904, under the auspices of the Society.

He was also a member of the Society of Arts and the Manchester Association of Engineers, and a Commissioner for the Navigation for the Upper Mersey. Mr. Hunter was of a deeply religious nature and was a devoted member of the Plymouth Brethren, frequently preaching and taking an active part in their meetings in Lancashire and Cheshire. A strenuous business man, he was noted for his gentleness and courtesy as husband, father, and host, and his love for children and their love for him was a frequent cause of remark. He is survived by his widow and three children.

Mr. Hunter was elected a Member of the American Society of Civil Engineers on February 7th, 1906.

JAMES EDGAR JENKINS, M. Am. Soc. C. E.*

DIED JULY 5TH, 1917.

James Edgar Jenkins was born in Vernon, N. Y., on November 25th, 1878. He received his early education in the Vernon schools, and was graduated from the village High School in 1896.

His father, Josiah W. Jenkins, is a well-known surveyor and hydraulic engineer, and from him the boy learned the rudiments of engineering so well that he qualified as Rodman with the United States Deep Waterways Survey, on which work he was engaged during 1897-98.

In 1898, the Utica Gas and Electric Company undertook the hydroelectric development of West Canada Creek, at Trenton Falls, N. Y., and, for nearly three years, Mr. Jenkins was Instrumentman and Inspector on this project.

In the mid-term of 1900, he entered Rensselaer Polytechnic Institute where he quickly overtook his class, and was graduated in excellent standing with the degree of C. E. in 1904. During his summer vacations he was employed as Instrumentman on the Rutland Canadian Railroad and the Fort Plain, N. Y., Water-Works.

Immediately after his graduation, Mr. Jenkins entered the employ of the engineers in charge of the Pennsylvania Railroad Tunnels, in New York City, as Rodman, and shortly became Chief of Alignment on the East River Division. This led to a position as Engineer with the Naughton Company and Arthur McMullen, on Sections A and B.

For the next three years he was Engineer for the Thomas Crimmins Contracting Company, on Barge Canal Contract No. 9 and on several minor contracts in New York City.

Mr. Jenkins was then employed as Engineer for Smith, Hauser, Locher and Company, on Aqueduct Contract No. 66, which position he retained for nearly three years. While engaged on this work his health began to fail, due to pulmonary trouble, and he sought to regain it by a stay at Southern Pines, N. C. This sojourn was shortened, in order that he might undertake the alterations of the dam, spillways, etc., of the Union Manufacturing and Power Company, on Broad River, South Carolina.

Shortly thereafter, in March, 1915, Mr. Jenkins became Superintendent for the Cook Construction Company, on Contract No. 2 of the Montreal Aqueduct Enlargement. When this work was closed down by war conditions, he returned to New York and, after a brief rest, took charge of the erection of a large concrete chemical mill at

* Memoir prepared by H. R. Beebe, Assoc. M. Am. Soc. C. E.

Buffalo for the contractors, the John W. Cowper Company. This contract was carried out during the winter of 1916-17, and on the completion of the work Mr. Jenkins' health was so precarious that he returned to his home in New York to recuperate. Shortly afterward, however, he became associated with the writer in constructing a roundhouse at North White Plains, but, before its completion, he was obliged to leave for a sanitarium at Saranac Lake, N. Y., at which place he died of tuberculosis, on July 5th, 1917.

From the foregoing summary of his activities, it will be noted that Mr. Jenkins was never idle. In his spare moments, he was a frequent visitor to the Society House, and had a large acquaintance among the members. He was of an inventive turn of mind, and had patented several devices along mechanical lines, including an automatic flashboard and a snow-melting furnace. This furnace he had intended to try out on a commercial scale during the coming winter, and it was expected that it would be so efficient that large numbers would be used in competition with the ordinary methods of snow removal.

Mr. Jenkins' early death was due in large part to his unwillingness to recognize the signs of failing health. He seemed to have a conviction that his body was a machine which, with minor repairs, could be run indefinitely, and that overhaul could be put off safely until his complete convenience. In spite of ill-health, his mind and judgment were not affected, and his cheerfulness was the admiration of all who knew him. That his career was cut so short is a source of deep grief to his friends and to those acquaintances who recognized in his professional attainments the promise of a bright future.

In June, 1907, Mr. Jenkins was married to Miss Helen Day, of New York City. He is survived by his widow and two children, a girl of seven and a boy of five, and also by his parents, Mr. and Mrs. J. W. Jenkins, of Vernon, N. Y., and one sister, Mrs. Carl H. Dudley, of Silver Creek, N. Y.

Mr. Jenkins was elected an Associate Member of the American Society of Civil Engineers on December 5th, 1906, and a Member on March 14th, 1916.

WALTER KATTÉ, M. Am. Soc. C. E.*

DIED MARCH 4TH, 1917.

Walter Katté was born in London, England, on November 14th, 1830. He was the son of Edwin Katté, and the grandson of Edwin Katté, a political refugee from Prussia during the reign of Frederick the Great. His mother, Isabel Chambers, was the granddaughter of John Chambers, a celebrated boat builder on the Thames, London. Walter Katté was educated in Kings College School, London, and, after his graduation, spent three years as an apprentice in the office of a civil engineer.

In 1849, he came to the United States and entered American railroad service as Clerk and Draftsman for the Chief Engineer of the Central Railroad of New Jersey, from Whitehouse to Easton, Pa. Later, he served as a Rodman and Assistant Engineer on the Belvidere and Delaware Railroad. In the early Fifties, he acted as Engineer for a land development company, and laid out the Town of Deerman, now Irvington-on-Hudson, N. Y.

During the three years following 1854, Mr. Katté was Chief Assistant Engineer on the Western Division of the Pennsylvania Railroad. Later, he acted, successively, as Resident Engineer of the Pennsylvania State Canals, as Assistant Engineer of the Pittsburgh, Fort Wayne and Chicago Railroad, and the Pittsburgh and Steubenville Railroad, until the breaking out of the Civil War.

In 1859, he was married, in Greensburg, Pa., to his first wife, Margaret Jack, who died in 1864, leaving one son.

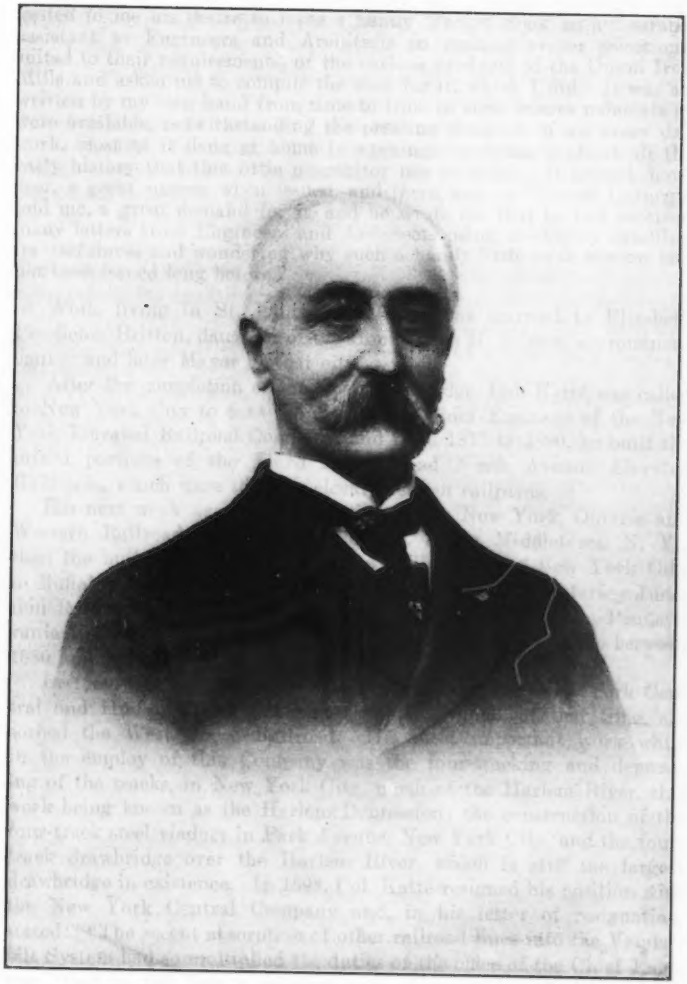
During 1861 and 1862, Mr. Katté served as a Colonel of Engineers in the Union Army, being commissioned from civil life to a staff position. He was assigned to bridge work in Washington, D. C., and at various points in Virginia and Maryland. He was the engineer in charge of the construction of the so-called "Long Bridge" over the Potomac River at Washington. While in this position, he had an experience with the great cavalry leader, General Philip Kearny. Returning one night from Washington to his regiment, which was quartered across the Potomac, the General sent his orderly ahead to demand passage over the bridge and received word that it was not in condition for traffic. He immediately rode his horse at full speed on to the bridge and, on being stopped peremptorily by Col. Katté, demanded an explanation as to why he was not permitted to proceed. Col. Katté quietly explained that a gap of 100 ft. or more in the bridge structure

* Memoir prepared by George W. Kittredge, M. Am. Soc. C. E.

would prevent his further progress, except by swimming. Commenting editorially, a New York daily paper said:

"In the Civil War nothing was more important to the safety of Washington than keeping the railroads and bridges in its neighborhood in perfect shape. This work Col. Katté supervised efficiently. Though not won on the battlefield, his military title stood for active, energetic work in the interests of military defense."

In 1863, Col. Katté was engaged as Chief Engineer of the Lewiston Branch of the Pennsylvania Railroad, and, later, as Resident Engineer and Engineer of Bridges and Buildings on the Northern Central Railroad, from Baltimore, Md., to Elmira, N. Y.



Col. Katté compiled and wrote the first "Carnegie Pocket Companion" published, and, recently, at the request of the Carnegie Steel Company, wrote the history thereof, as follows:

"In 1865 to 1868, I was resident in Pittsburgh as Engineer and Secretary of the Keystone Bridge Company. In 1868, that company and the Union Iron Mills of Pittsburgh (Carnegie Bros., Kloman, Phipps & Co.) decided to enter the western field in competitive business and to establish an office and representative in Chicago for that purpose; I was chosen for that position. The Keystone Bridge Company had at that time already under contract the manufacture and erection of the superstructures of the Hannibal & St. Joe Railroad Company's bridge over the Missouri River, at Kansas City, and the Illinois Central Railroad Company's bridge over the Mississippi River, at Dubuque, Ia., also was negotiating contracts for bridges, later consummated, for Mississippi River at Keokuk, Ia., Louisiana, Mo., and St. Louis, Mo.

"I proceeded to Chicago and opened there the western office of the Keystone Bridge Company and the Union Iron Mills, of Pittsburgh, Pa., and took personal charge, as agent and representative, of the field operations under these contracts.

"In 1870, negotiations for the great steel arch bridge over the Mississippi River at St. Louis were being actively promoted by Mr. Andrew Carnegie and myself, and finally consummated in the execution of a contract, signed by Capt. James B. Eads, as President of the Illinois & St. Louis Bridge Company, and by myself, on the part of the Keystone Bridge Company, under the terms of which, the Keystone Bridge Company undertook and obligated itself to perfect the mechanical details of the shop drawings of the superstructures, supply all materials for, and manufacture of, same, design plans for erection, and to erect it and assume all responsibility for the successful completion of the erection.

"I was assigned to take personal charge, as Resident Engineer, of said erection. As the responsibility for the successful consummation of same was of extreme gravity, I felt the paramount necessity of my personal presence on the work continuously, which, of course, resulted in the closing of my office in Chicago and the removal of same to St. Louis, which was effected early in 1871, and the joint Western office of the Keystone Bridge Company and the Union Iron Mills, of

WALTER KATTÉ

Pittsburgh, Pa., was opened under my charge at No. 211 Washington Avenue, St. Louis, Mo.

"About this time, or a little later, Mr. Thomas Carnegie suggested to me his desire to issue a handy 'Pocket Book' as a desirable assistant to Engineers and Architects in making proper selections, suited to their requirements, of the various products of the Union Iron Mills and asked me to compile the mss. for it, which I did. It was all written by my own hand from time to time in such leisure moments as were available, notwithstanding the pressing demands of my every day work, most of it done at home in evenings—and that's about all the early history that this little progenitor has to claim. It proved, however, a great success when issued, and there was, so Thomas Carnegie told me, a great demand for it, and he wrote me that he had received many letters from Engineers and Architects using it—highly extolling its usefulness and wondering why such a handy little *vade mecum* had not been issued long before."

While living in St. Louis, Col. Katté was married to Elizabeth Pendleton Britton, daughter of the Hon. James H. Britton, a prominent banker and later Mayor of that city.

After the completion of the St. Louis Bridge, Col. Katté was called to New York City to take the position of Chief Engineer of the New York Elevated Railroad Company, and from 1877 to 1880, he built the initial portions of the Third Avenue and Ninth Avenue Elevated Railroads, which were the first elevated steam railroads.

His next work was the construction of the New York, Ontario and Western Railroad, from Weehawken, N. J., to Middletown, N. Y.; then the building of the West Shore Railroad from New York City to Buffalo, which was followed by the construction of the Jersey Junction Railroad, connecting the West Shore Railroad with the Pennsylvania Railroad, at Jersey City. This work occupied his time between 1880 and 1886.

In 1886, Col. Katté became Chief Engineer of the New York Central and Hudson River Railroad Company, which, at that time, absorbed the West Shore Railroad. His most important work while in the employ of this Company was the four-tracking and depressing of the tracks, in New York City, north of the Harlem River, this work being known as the Harlem Depression; the construction of the four-track steel viaduct in Park Avenue, New York City, and the four-track drawbridge over the Harlem River, which is still the largest drawbridge in existence. In 1898, Col. Katté resigned his position with the New York Central Company and, in his letter of resignation, stated: "The recent absorption of other railroad lines into the Vanderbilt System had so multiplied the duties of the office of the Chief Engineer, that he felt that a younger man was necessary for the work." In accepting his resignation, the Hon. Chauncey M. Depew, then President of the Railroad Company said: "Col. Katté is one of the fore-

most engineers in the world. He is still connected with the New York Central and Hudson River Railroad Company as Consulting Engineer, and will be as long as he lives."

Col. Katté was one of the original thirteen founders of the Western Society of Civil Engineers of which he only recently was elected an Honorary Member. He was also a member of the Institution of Civil Engineers, of Great Britain.

During his active engineering life, Col. Katté made frequent contributions to technical papers and to the *Transactions* of the National Engineering Societies. He published one of the first sets of standard specifications for railroad construction work, and had taken out several U. S. Patents, the one in most general use being his so-called "Three-tie rail joint."

Important daily papers at the time of Col. Katté's death were unanimous in their expression of the fine quality of his engineering work, one commenting editorially as follows:

"Col. Katté was a fine American, a great railroad uilder, and had won first place among our civil engineers * * *. He knew and cared little about the devious ways of financing railroads; everything about construction and operation. Half a century of such activity fairly earned a period of repose. Col. Katté's later years were peaceful, calm, uneventful. He will live in the memory of his profession as a man who saw things clearly and who did things thoroughly. That is, from the practical viewpoint, the highest of encomiums."

Col. Katté enjoyed nearly nineteen years in quiet retirement. His health was excellent, with the exception of almost total deafness; his mind alert and vigorous; his spirit strong and serene until the day of his death. He died at his home, in New York City, on March 4th, 1917, and is survived by a widow, two sons, and a daughter.

Col. Katté was elected a Member of the American Society of Civil Engineers on October 7th, 1868, and served as a Director in 1885 and 1889.

WILLIAM BYRD KING, M. Am. Soc. C. E.*

DIED OCTOBER 11TH, 1915.

Mr. King was born in Orange County, Virginia, on December 29th, 1848, and was a direct descendant of Colonel William Byrd, who founded Richmond in 1733.

His early education was through tutors and private neighborhood schools. Later, he took academic work at Locust-Dale College and some engineering courses at the University of Virginia.

In 1873 Mr. King went to Texas, where he engaged in land surveying, principally the demarcation of railway land grants in the Far West. He continued this pioneer work, under all sorts of hardships and dangers, until 1879, when he was appointed Assistant Engineer on Construction of the Texas and Pacific Railway, and later of the Fort Worth and Denver City Railway, and the Missouri, Kansas and Texas Railway, in Texas.

In 1884 Mr. King was appointed City Engineer of Fort Worth, serving until 1889, when he was appointed City Engineer of Waco, serving until 1891. During his incumbency of these two offices he planned street and sewerage systems that were basic for both municipalities.

After completing his work at Waco, Mr. King was called to the Chief Engineership of the Fort Worth and Rio Grande Railway, now a part of the Frisco System. Later, he was elected Vice-President and General Manager of the Frisco System in Texas, which position he filled with distinction until Armour and Swift established their great packeries and stockyards in Fort Worth, in 1902, when he was made President of the Fort Worth Belt Railway, and Vice-President and General Manager of the "Armour-Swift" Stockyards.

For several years Mr. King was a sufferer from arterio-sclerosis, and in 1915 was retired, with consultation duties only, on full salary. For perhaps two years before this he had suffered from the insomnia characteristic of his malady to the extent that 10 or 12 hours' sleep a week was his gauge of rest. In spite of this, he was regularly at his desk, the suave, courteous, directing head of the busiest cattlemart of the Southwest.

In addition to his other engagements, he found time during 1913 to act as a member of the Board of Engineers in charge of Fort Worth's new water supply. His work on that Board helped to bring to light and eradicate one of the most insidious pieces of municipal graft ever known in the South.

* Memoir prepared by John B. Hawley, M. Am. Soc. C. E.

During several of the quite strenuous Board meetings on this matter, he was obliged to retire to his physician's office and submit to copious bleeding, in order to keep his blood pressure within living bounds. Little things like letting out part of his heart's blood in order to stand the strain of serving the public did not seem to "cut any figure".

The writer knew "Byrd" King, with increasing intimacy, from 1891 until his death. He was the kind of man we all want really to have as a friend. An Engineer of the Tredgold type. A typical Southern gentleman? No. Byrd King's courtly manners marked him as the son of many generations of Virginia Cavaliers, but his gentleness went far beyond any qualification as to South or North: his innate, never spoken, but always to be depended on, rule of action was, *noblesse oblige*.

William Byrd King was a world gentleman.

Mr. King was elected a Member of the American Society of Civil Engineers on October 7th, 1896.

EUGENE CASTNER LEWIS, M. Am. Soc. C. E.*

DIED FEBRUARY 13TH, 1917.

On the left bank of the Cumberland River, about eight miles above Dover, the county seat of Stewart County, Tennessee, there may still be seen the ruins of the once famous Cumberland Iron Works, which were destroyed by the Federal Army after the capture of Fort Donelson, on February 16th, 1862.

In 1830, two brothers, John and Samuel Stacker, came from Pennsylvania to Tennessee, and in beginning this enterprise became the founders of the iron industry in this section of the State. With them came George T. Lewis, then a lad sixteen years of age. Thirty-two years later, this property had developed into a great domain of more than 60 000 acres, from which were obtained the ore, limestone, and charcoal used in its furnaces. The Hon. John Bell, James Woods, and the Yeatmans had become interested, and George T. Lewis was General Manager of the works and the affairs of the partnership. The chief product of the foundry was the massive iron kettles used in the manufacture of sugar in the Southern States and abroad. The furnaces supplied the charcoal, pig iron, and blooms used in the foundry and rolling mill, the surplus being sold on the market. The product of the rolling mill was bar iron of exceptionally high quality. About 500 slaves and many employed men supplied the labor.

Mr. George Thomas Lewis, the efficient Manager of this great property, and his wife, who was Miss Margaretta Barnes, of Philadelphia, Pa., were the parents of six children, all born at their home at the Cumberland Iron Works. The fourth child, born June 22d, 1845, was Eugene Castner Lewis, the subject of this memoir.

Born and reared in the very midst of organized and productive labor, the young lad inhaled with the air that he breathed the instinct and inspiration that abided with him through all the stirring years of his life. His motives and purposes were ever for production and construction; never for the reverse.

At his father's home, and at a private school in the neighborhood, he learned the rudiments of education. This was followed by a course at Stewart College, in Clarksville. Then came the four years of war between the States. Fort Donelson, only nine miles from his home, was the scene of fierce fighting and final capture. The gunboats came up the river, and his father, bound and taken as a prisoner on one of them, was forced to face and witness the destruction of the plant, the work of his lifetime. Thrilled with anger and indignation, the lad,

* Memoir prepared by the following Committee: Wilbur F. Foster, Hunter McDonald, John Howe Peyton, and Richard Montfort, Members, Am. Soc. C. E.

Eugene, was so unguarded in his talk, so eager to help the Confederates, that he was threatened with imprisonment. This, however, was waived on condition that he be sent out of the State; and thus it was that Eugene became a student at the Pennsylvania Military Academy, then at West Chester, Pa., from which he was graduated with the Class of 1865 as one of ten, most proficient in mathematics and kindred studies. Here, also, he acquired a title, due perhaps to his proficiency, popularity, or characteristic leadership, a title that stayed with him to the end of his days, and for more than fifty years he was only and always known as "Major Lewis." No other title seemed to fit.

With very brief delay after his graduation from the Military Academy, Major Lewis began his professional career, in October, 1865, in the service of the Memphis, Clarksville, and Louisville Railroad, as Assistant Engineer, with the late William D. Pickett, Hon. M. Am. Soc. C. E.

In May, 1866, he entered the service of the Louisville and Nashville Railroad, as Assistant with the late Rudolph Fink, M. Am. Soc. C. E., in the Road and Engineering Department, and, from October, 1869, until November, 1870, he was in charge of the construction of the Glasgow Branch of that road.

He was then engaged in making surveys for three projected lines of railroad in Western Tennessee and Northern Mississippi until July, 1871, when he was placed in charge of the construction of the road which is now the Owensboro and Russellville Division of the Louisville and Nashville Railroad.

On completion of this service, Major Lewis withdrew from strictly professional engagements as a Civil Engineer; and, yet, in the multifarious affairs of his active life, his education for the Profession, together with his native talent, experience, and close study of engineering work, constituted a most important factor in his equipment for the conception, organization, and successful accomplishment of the many notable achievements in which his skill and training as a Civil Engineer were in constant service.

As the business member of the firm of W. B. Read and Company, Major Lewis was engaged, in 1873-74, in the execution of a contract for the construction of certain sections of very heavy work in Kentucky, on the railroad which is now a part of the Queen and Crescent System.

Through the large purchase of explosives used on this work, Major Lewis became favorably known to the Dupont Powder Company. This led to the acquaintance and personal friendship of its owners, and to his appointment as their agent for the sale of the product of their subsidiary mills at Sycamore, in Cheatham County, Tennessee, and,

later, to his entire control and management of that property, until, in 1904, manufacture at that plant ceased, and the mills were dismantled.

Sycamore Mills was the business headquarters and residence of Major Lewis from 1875 to 1897, and, during the summer, until 1907. The memory of his public spirit and usefulness is cherished and honored in that community, where the many improvements in highways, bridges, and other details still bear testimony to his skill, energy, and good judgment. It was in the reconstruction of one of these bridges that the accident occurred which finally cost him his life.

It was during the period of his engagement in this enterprise that Major Lewis was married, on October 12th, 1880, to Miss Pauline Dunn, of Nashville, Tenn., and, at their home at Sycamore, seven children were born, all of whom are living. Mrs. Lewis died at Nashville, on January 14th, 1902.

In the executive department of railways, Major Lewis served with great ability and success: On December 8th, 1896, he was elected a member of the Board of Directors by the Stockholders of the Nashville, Chattanooga, and St. Louis Railway, and served faithfully and efficiently in that capacity until his death. He was Chairman of the Executive Committee from December 14th, 1898, to October 13th, 1914, and was "Chairman of the Board" from February 28th, 1906, until his death. Twice the duties of Acting President were added to his other service; first, from February 17th to February 28th, 1906; and, again, from December 19th, 1913, to April 1st, 1914.

For more than 30 years, Major Lewis possessed the friendship and confidence of the chief officials of the Louisville and Nashville Railroad System, and by them was entrusted with the care of its interests in many matters of importance, especially in its affairs, and the development of its facilities in Tennessee. An important item in this service was the following:

"The Louisville and Nashville Terminal Company" was chartered on March 22d, and organized on March 28th, 1893, for the purpose of perfecting joint terminal facilities for the use of the Nashville, Chattanooga, and St. Louis Railway, and the Louisville and Nashville Railroad, and the erection of the necessary buildings required for the joint or separate use of those roads.

The steps preliminary to the purposes of this charter were all under the personal direction of Major Lewis, and extended over a period of several years, required for the purchase of the necessary real estate. Major Lewis was made President of the Company, on March 2d, 1898, and served in that office until November 27th, 1905. In that capacity, he had responsible control of every detail, including the approval of all plans and designs, and the awarding of contracts; also, the general supervision of grading the grounds, construction of the

Union Passenger Station and other extensive buildings, steel viaducts, bridges, yard trackage, and other details, altogether involving an expenditure of more than $2 500 000. This work was begun in August, 1898, and formally opened for service in October, 1900.

The Nashville and Decatur Railroad, beginning at Nashville, Tenn., and ending at Decatur, Ala., is under lease for a long term of years to the Louisville and Nashville Railroad, but the organization of the Lessor Company is maintained, and, of this, Major Lewis was a member of the Board of Directors, and Vice-President at the time of his death.

The Napier Iron Works are in Lewis County, Tennessee, and, from the time of its organization in 1890, until 1895, Major Lewis was President of the Company and General Manager of the works. A branch line of the Louisville and Nashville Railroad was built from Summertown to Napier, and the furnace plant at that place was built and operated as a charcoal furnace until 1895 under his management.

By the Courts, Major Lewis was entrusted with the following responsible duties:

In 1901, he was made Co-Receiver in the affairs of the Nashville Street Railways. This resulted in the re-organization of the Company under the title of The Nashville Railway and Light Company, in 1903.

In June, 1910, he was appointed Co-Receiver in the affairs of the Bon Air Coal and Iron Company. In the performance of this trust, he continued until his death.

It is probable that his notable success in the organization, development, and management, as Director General, of the Tennessee Centennial Exposition, held at Nashville in 1897, is the especial achievement by which Major Lewis was most widely known, and for which he justly received the greatest commendation from the public.

It is impossible, in this memoir, to give adequate or even partial description of this memorable and historic event and its far-reaching influence for good. Suffice it to say that it was the unanimous and unqualified action of the large and very able Board of Directors, as well as the voice of the people at large, that the complete success of the Exposition was, in great measure, due to the skill, inventive genius, and admirable taste of Major Lewis in the design and construction of details, and to his rare administrative ability in the management of its affairs.

As a natural consequence, and under the inspiration of the example set in the attractive beauties of the Exposition grounds, there came the creation of the Park System of the City of Nashville; and from 1901 to 1913, Major Lewis was the moving spirit, the presiding genius of the Board of Park Commissioners. Evidence of his taste, skill, and originality is seen in numberless det ils, sometimes unique,

always attractive, in the many Parks of Nashville, to which he devoted much time and study. At the Centennial, "The Parthenon", an accurate reproduction of the original at Athens, still stands as a memento of the Exposition.

The Nashville American had long been the leading morning daily newspaper of the city. In 1896, Major Lewis became its owner and publisher, and continued as such until 1909. Under his management, it was a vigorous and influential advocate of the policies of the political party of which it was the organ, and of integrity and "up-to-date" methods in municipal affairs. One especial reason for its purchase in 1896 was for its service in the Publicity Department of the Centennial Exposition.

The Engineering Association of the South was organized at Nashville, on September 18th, 1889, and Major Lewis was one of the charter members. He served as Director for several terms, and was President of the Association in 1893.

The following are some of the personal attributes of Major Lewis, which combined in the formation of a character, aggressive, public spirited, and of conspicuous usefulness in public affairs and in private life: Strict integrity and faithfulness in official station, and in matters of public or private trust; and, in this, he was imperative in demanding the same from colleagues and subordinates. Fearless disregard of public opinion or criticism, in advocating or executing measures which, in his judgment, were commendable and right; independence of thought, and great originality in conception, design, and methods; untiring energy and industry. His active mind, dominating a somewhat frail physique, seemed never to be at rest.

At his home, there was ever a rare and genial hospitality and an unfailing and active interest in the welfare of the people among whom he lived.

Major Lewis was gifted with correct taste and appreciation of works of art, and was a liberal subscriber to funds for the promotion thereof, as well as to other measures of public character. His private charities are known to have been large, but were ever carefully concealed.

Briefly, Major Lewis was public spirited, self-reliant, masterful, fearless, outspoken, faithful in duty, talented, successful, charitable, and honorable in all his dealings.

Like all men of strong character, he was not faultless, nor without vigorous opponents and some personal enemies; and, yet, by one and all, his death was felt to be a calamity; and his imperative dictation, that there should be "no flowers, no funeral, no fuss" when he should pass away, could not prevent the large attendance of eminent men, long-time associates, and warm-hearted friends, from near and far,

at the brief but deeply impressive service, when, at the twilight hour, his remains were placed in the family vault at Mt. Olivet.

Then, too, as the twilight faded, for 300 sec. all traffic ceased, no wheels were in motion, on the entire system of the Nashville, Chattanooga, and St. Louis Railway, and on the street railways of the City of Nashville.

Major Lewis was elected a Member of the American Society of Civil Engineers, on March 5th, 1873, and served as a Director in 1903-05 and 1912-14. He valued his membership in the Society very highly, and, until his death, maintained an active interest in its affairs.

ALEXANDER WILLIAM MacCALLUM, M. Am. Soc. C. E.*

DIED FEBRUARY 3D, 1917.

Alexander William MacCallum was born in Edinburgh, Scotland, on July 25th, 1859.

He served an apprenticeship of four years to a mechanical trade at the shops of the Central Railroad of New Jersey, at Ashley, Pa. This apprenticeship was finished in 1881, and he then entered Lafayette College, at Easton, Pa., from which he was graduated in June, 1885, with the degrees of C. E. and M. E.

During 1886, and a part of 1887, Mr. MacCallum was employed as Engineer and Assistant Superintendent at the Massillon Engine Works.

In 1887 he was engaged by Samuel R. Bullock and Company, of New York City, as Engineer and Superintendent of the water-works at Massillon, Circleville, and Defiance, Ohio, thus entering the field of water-works engineering, in which he afterward specialized.

In March, 1889, Mr. MacCallum was appointed Engineer and General Manager in charge of all the public utilities of R. D. Wood and Company. While in this position, he supervised the building and rebuilding of many of that Company's water-works plants, as well as the management of several of its gas and light plants, including those at Denison, Tex.; Mobile, Florence, and Tuscaloosa, Ala.; Pensacola, Tampa, and Lake City, Fla.; Macon, Ga.; Vincennes and Greencastle, Ind.; Sharon, Corry, Chester, and Marcus Hook, Pa.; Owego, N. Y.; and Millville, N. J.

On numerous occasions, he acted as Appraiser and Arbitrator for various companies, notably for the Trinidad, Colo., Water-Works (1896); the Macon, Ga., Gas Light and Water Company (1910); the Warren, Pa., Water-Works (1911); the Ashland, Ky., Water Company (1911); as well as the Kane, Pa., Water Company, the Catlettsburg, Kenova, and Cereda, W. Va., Water-Works, etc.

From March, 1906, until his death, Mr. MacCallum was Consulting Engineer and General Manager, in charge of a number of public utilities for financial interests, with headquarters at Philadelphia, Pa., devoting his spare time to valuations and appraisals and to examinations and reports, for bankers and private investors, on water-works properties in various States. He was probably best known as the Secretary and General Manager of the New Chester Water Company, of Chester, Pa., and also of the Linwood, South Chester, Ridley,

* Memoir prepared by the Secretary from information furnished by George W. Fuller, M. Am. Soc. C. E., Robert C. Wheeler, Assoc. M. Am. Soc. C. E., and Harry S. Hopper, Esq.

Chichester, Edgemont, and Delaware Water Companies, and of the Greencastle and Vincennes, Ind., Water Corporations.

On February 3d, 1917, while apparently in the best of health, Mr. MacCallum suffered a stroke of apoplexy which caused his death.

On October 13th, 1887, during his residence in Massillon, Ohio, Mr. MacCallum was married to Grace F. Weaver, of Cleveland, Ohio. He is survived by his wife and five children, Mrs. Nellie Williams, Jane Gordon, Grace Elizabeth, Walter Wood, and Alexander William MacCallum, Jr.

His most striking characteristic was his cheerfulness and optimism and his devotion to his work, his family, and his immediate friends, among whom his loss will be keenly felt. Although exceedingly modest and retiring, he was withal a shrewd business man. He used sound judgment in the application of his engineering knowledge in the water-works field, and won the confidence alike of citizens and public officials, as well as of his associates, in the management of the various water-works properties. Under his quiet manner, however, Mr. MacCallum had great strength of character, devotion of purpose, and deep religious convictions.

He had made his home at Merchantville, N. J., for many years, and always took an active interest in local public affairs. Among other things, he served for a long time as a member of the Sewerage Commission which inaugurated and constructed the improved sewerage system for the town.

At a meeting of the Executive Committee of the New Chester Water Company, on February 21st, 1917, Mr. Harry S. Hopper, the Treasurer of the Committee, who was also an intimate friend of Mr. MacCallum, made the following statements:

"It is with a feeling of deep sadness that I report the sudden death on February 3d, 1917, of our late Secretary and General Manager, Mr. Alexander W. MacCallum.

"The loss of Mr. MacCallum seems irreparable to me personally, and also to the Water Works he managed, as well as the Water Works community generally. He was connected with our interests for nearly 30 years, and was much more than the title given him indicates. He took a deep personal interest in each plant and could not have been more faithful and painstaking had he owned the properties. He always put the 'ladies' first, meaning Mrs. Little, Mrs. Lippincott, and Mrs. Hopper, and never spared himself where their interests were involved.

"He built the properties up in the last ten years to a point of efficiency and profit toward which he had been aiming, and looked forward to the completion of the work planned at Chester as the crowning effort of his life; it is difficult to understand why he should not have been allowed to realize his desire."

The following resolutions were also unanimously adopted at the meeting:

"*Resolved,* That, in the death of Mr. MacCallum the Company has met a loss that cannot be supplied. Mr. MacCallum's character included an extraordinary combination of qualities. To a thorough technical knowledge of the scientific branches of the business, which he had acquired as engineer, he united the broad knowledge of business, which he had earned by conscientious devotion to work, and he had also the higher qualities which the experience of responsibility cheerfully and successfully borne brings to all. His sympathy with human nature was deep and evident, and his qualities of friendship were sincere and enduring.

"*Resolved,* That the Board desires to extend its deepest sympathy to Mrs. MacCallum and her family, and directs that a copy of these resolutions be forwarded to her."

Mr. MacCallum was elected a Member of the American Society of Civil Engineers on September 2d, 1914.

DANIEL McCOOL, M. Am. Soc. C. E.*

DIED NOVEMBER 30TH, 1916.

Daniel McCool was born at London, Ont., Canada, on January 9th, 1850. He was educated at the Jesuit College in Quebec, and, later, was graduated from the English High School in that city.

In 1869, Mr. McCool moved to Niagara Falls, N. Y., and later to Auburn, N. Y., and his first engineering experience was gained as Rodman on the fortifications at Point Lewis where he was employed for two years.

He then entered the employ of the New York and Oswego Midland Railroad Company as Assistant Engineer on construction. In 1873, he became Assistant Resident Engineer on the New York Central and Hudson River Railroad, in which position he had charge of the four-track improvement west of Syracuse, N. Y., under the Chief Engineer. During the last five years of his service with this Company, Mr. McCool, in addition to his engineering duties, served as Assistant Superintendent in charge of traffic.

In 1880, Mr. McCool was appointed Private Secretary to the General Manager of the Michigan Central Railroad and also had charge of the Engineering Department of the Company. While in this position, he designed and constructed the new freight yards and stockyards at Detroit and made the plans for the new Passenger Station at that place, as well as the improvements connected therewith.

In 1882, he entered the service of the Detroit, Mackinaw and Marquette Railroad Company as General Superintendent and Chief Engineer. In this capacity he had charge of the car ferry service over the Straits of Mackinac, and introduced the first successful ice-crushing craft, by placing a propeller at the bow as well as at the stern of the ferry. While in the employ of this Company he extended the line to Ishpeming and Negaunee, Mich., in order to tap the extensive iron mines in that region.

In 1885, Mr. McCool was made General Manager of the St. Joseph and Grand Island Railroad, with headquarters at St. Joseph, Mo. He was also President of the St. Joseph Terminal Company, and built the Kansas City and Omaha Railroad, a distance of 200 miles, as a feeder to the St. Joseph and Grand Island.

In 1888, he became General Manager of the Santa Fé and California Railroad, and during his connection with that Company added 100 miles to its lines.

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

In 1889, Mr. McCool retired from railroad work and made an extended tour in Europe. On his return to the United States, he organized, in 1898, the Newaygo Portland Cement Company, at Newaygo, Mich., with which he was identified at the time of his death, having served as its President for many years and having been largely instrumental in putting it on a paying basis. Under his direction, the marl beds near Newaygo, belonging to the Company, were developed, the local power dam was built, and the great plant of the Company was constructed. In addition to his work as President of the Newaygo Portland Cement Company, Mr. McCool was prominently identified with the Edison Electric Light Company, of Grand Rapids, Mich., of which he became President in 1901. He was also interested in many other local enterprises.

In the summer of 1899, Mr. McCool sustained serious injuries in a runaway accident from which he never fully recovered. A short time before his death, he had entered the Henry Ford Hospital, at Detroit, Mich., for treatment, and had returned to his home in Grand Rapids apparently greatly improved. He had continued actively in the business of the Newaygo Portland Cement Company and had visited the plant only a few days before the brief illness which caused his death.

Mr. McCool is survived by his widow, who was Miss Kate Fisher, of Batavia, N. Y., and one brother, Mr. William A. Tench, of Detroit, Mich.

In Grand Rapids and Newaygo, Mr. McCool was widely known for his benevolent and philanthropic work, having been actively identified with many charitable movements in both places. In the business world his influence was strong and progressive, and he commanded high esteem among men of large affairs. His funeral took place at Batavia, N. Y., and out of respect for him who had been its founder and President, the hour was marked by the complete cessation of operations at the plant and power house of the Newaygo Portland Cement Company.

Mr. McCool was elected a Member of the American Society of Civil Engineers on September 5th, 1883.

THEODORE HALL McKENZIE, M. Am. Soc. C. E.*

DIED MAY 3D, 1916.

Theodore Hall McKenzie was born in Yalesville, Conn., on March 29th, 1847. His father, William McKenzie, was a native of Scotland, who came to America when a young man and engaged as a contractor in the construction of buildings and stone bridges. His mother, Temperance (Hall) McKenzie, was a descendant of an old Connecticut family, and had great strength of character.

During boyhood, Theodore Hall McKenzie attended schools in Wallingford and Meriden, Conn., and, later, took the Scientific Course at the Literary Institute, in Suffield, where he studied Surveying. When still a lad, he read many scientific books, and during 1866-68 he assisted his father in the construction of public works.

From 1868 to 1872 he worked with location and construction parties on several railroads in Connecticut and Massachusetts. During this period, he took private lessons under professors of the Sheffield Scientific School of Yale. He then became, for two years, Division and Resident Engineer on the Providence and Springfield Railroad. From 1875 to 1878, he was City Engineer of Meriden, Conn., where he prepared plans, under the direction of the late E. S. Chesbrough, Past-President, Am. Soc. C. E., for the sewerage of that city, and also built reservoirs for an addition to its water supply.

In 1878 Mr. McKenzie was elected Secretary of the Peck, Stow and Wilcox Company, hardware manufacturers, of Southington, Conn., which position he held for 10 years. During this period, he designed and built the water-works of Southington and Plainville. He also planned a sewage disposal plant for Meriden, which was the first in Connecticut. A paper on "The Water-Works of Southington, Connecticut",† was written by him and presented before the Society.

After 1888, Mr. McKenzie maintained offices in Southington and Hartford, and served as Consulting Engineer on the construction of fourteen water-works and twelve sewerage systems. Among these may be mentioned the water-works at Naugatuck, Litchfield, Wallingford, Simsbury, Terryville, Newton, and South Manchester, Conn., and Brewster, N. Y.; sewage disposal plants at Manchester, South Manchester, Norfolk, Bristol, Ridgefield, and Sharon, Conn., Johnstown and Gloversville, N. Y., and Princeton, N. J.; also water-power developments at Berlin, Conn., and Croton Falls, N. Y. Since 1906, he had been largely engaged in the appraisal of mills and water power on the Croton and Ashokan water-sheds for the supply of the City of New

* Memoir prepared by Mansfield Merriman, M. Am. Soc. C. E.

† *Transactions*, Am. Soc. C. E., Vol. XV (1886), p. 885.

York, and on similar work for the Barge Canal in New York State. He was frequently an expert witness in litigations regarding such property.

In 1887, the Legislature of Connecticut constituted a State Board of Civil Engineers to inspect dams and to approve plans for new dams and reservoirs; Mr. McKenzie was a member of this Board for more than a quarter of a century, and, during part of that time, he was its Chairman.

Mr. McKenzie was Secretary and Superintendent of the Southington Water Company for 27 years, and Secretary and Manager of the Terryville Water Company for 4 years. He served as the Engineer Member of the Connecticut State Board of Health for 20 years. He was a member of the Connecticut Society of Civil Engineers, of the New England Water-Works Association, and of the American Public Health Association. He was also a member of the Masonic fraternity, and of the Baptist Church.

He was a hard worker in his profession, but, in his home, he loved the recreation of music, and out-of-doors he regarded horses as one of the best relaxations from the cares of life. His favorite counsel to young men was to learn thoroughly some business or profession and to abstain entirely from tobacco and liquors. Mr. McKenzie was held in esteem by his business associates and by the community in which he lived on account of his high character and pleasing personality.

He died suddenly, from an attack of heart disease, in his office in Southington, shortly after having arrived there to begin the work of the morning.

Albert B. Hill, M. Am. Soc. C. E., of New Haven, Conn., writes as follows regarding Mr. McKenzie:

"I was not intimately acquainted with him and was never associated with him on any work, although I was on the opposite side in several water cases. His services were much in demand as an expert in hydraulic cases, not only in his own State but in neighboring States. He was very zealous for the interests of his clients and considerate of his opponents.

"He had a very pleasant, agreeable personality, and will be greatly missed in New England engineering circles."

Robert E. Horton, M. Am. Soc. C. E., of Albany, N. Y., writes as follows:

"I knew Theodore H. McKenzie quite intimately during the period from 1906 until the time of his death. My association with him was largely in the matter of preparation of technical evidence in water-power claims on Esopus Creek. However, he was also associated with me in the defense of certain water-power and flood claims arising from the construction of the Barge Canal, we being both employed by the State of New York on these matters. We were also associated on certain matters involving water-power and water supplies, quite a number

of matters, in fact, in New England. I would say of Mr. McKenzie that one might on first acquaintance easily misjudge him because of his inclination to be apparently brusque and very direct and frank in anything he had to say. The frankness and directness were true characteristics of the man. The brusqueness was apparent, not real, as on better acquaintance he was found to be exceedingly genial and cordial, in fact, I have known but few men who were so carefully and consistently loyal and devoted to their friends as Mr. McKenzie.

"In professional work Mr. McKenzie may be said to have belonged to the older school of practical engineers. The methods which he adopted for the solution of problems were nearly always simple and direct. He had had a very wide experience in engineering work in certain lines, especially water supply, sewerage, and water-power work. This experience had given him most excellent judgment in matters to which it related. He would reach conclusions at times in so simple and direct a manner as perhaps to arouse suspicion on the part of some of the younger generation who believe that correct results in similar matters can only be reached through long processes of calculation. To one, however, who knew Mr. McKenzie's rich experience, his judgment would be most highly esteemed.

"Mr. McKenzie was at times somewhat severe in his criticism of those whom he believed to be dishonest or unprincipled in their actions. He was himself apparently incapable of anything but absolute frankness. This trait was often evident in his work as an expert witness, wherein he would very readily admit any necessary qualification of testimony he had given which was brought to his attention. This was at times perhaps a little distressing to attorneys with whom he was associated, but, on the other hand, he numbered among his most steadfast friends many attorneys prominent in the trial of technical cases, both those with whom he had been associated and those whom he had opposed."

On October 11th, 1871, Mr. McKenzie was married to Mary E. Neal, daughter of Roswell A. and Eunice (Atkins) Neal, of Southington, Conn. She survives him, with two sons, Samuel H. and William A. McKenzie, and two daughters, Eunice J. and Fanny L. McKenzie.

Mr. McKenzie was elected a Member of the American Society of Civil Engineers on September 7th, 1881.

STANLEY ALFRED MILLER, M. Am. Soc. C. E.*

DIED MAY 13TH, 1917.

His many friends and associates were shocked beyond measure by the dreadful tragedy which culminated in the death of Stanley Alfred Miller and his assistant, Mr. Epaphroditus Hawkins, which took place about 42 miles from La Romana, Santo Domingo, on the morning of May 13th, 1917.

Stanley Alfred Miller was born in New Orleans, La., on May 27th, 1882, of one of the fine old families which have made his native State so famous by their ideals and accomplishments, and whose traditions he consistently maintained. He was educated at local schools and at the Louisiana State University, where he was one of the youngest students.

His professional work began like that of most engineers, as Rodman, Levelman, Instrumentman, etc. Then, he was Assistant Engineer on sewers, and on levee construction and railways. At the age of 19, however, Mr. Miller was Assistant Engineer to the Board of Public Works of Mobile, Ala., engaged in design and construction. As Assistant to various consulting engineers he was employed on the survey, design, and construction of sewers and water-works for Baton Rouge, La., Mobile, Ala., Dallas, Tex., and Ardmore and South McAlester, Okla. In 1904, he served as Resident Engineer on the Chihuahua and Pacific Railroad, and, in 1905, he was with S. Pearson and Son, Limited, Contractors, of London, England, on the construction of Port Works at Coatzacoalcos (now Puerto, Mexico), having been for a time in direct charge of the contractors' labor forces on the terminal yards and jetties. This will be recognized by all engineers as a position of great responsibility for a man of his age.

This was followed by his work for the Mexican Light and Power Company, near Necaxa, Mexico, in 1906, in local charge of the construction of Earth Dams Nos. 1 and 3, and Tunnel No. 1, where his infinite care and attention to every detail proved to be the source of much valuable information to his associates.

While living in the semi-permanent camp near the dams, Mr. Miller was returning to his quarters after a midnight inspection of some of the work, when he stumbled over a severely wounded Mexican laborer. Having no assistance, and in spite of the fact that he was not a large man physically, he picked up the wounded man, carried him to his own cabin, and telephoned for a doctor. It was raining heavily, and the doctor was miles away attending to other patients, so Mr. Miller, by the light of a flickering and temporary arc lamp, dressed the abdom-

* Memoir prepared by Verne LeRoy Havens, M. Am. Soc. C. E.

inal wounds, the operation requiring many stitches. The man was doomed in any event, but Mr. Miller's efforts maintained the spark of life until his family could get to him.

Mr. Miller was engaged in the construction of a 7-mile sewer for Paducah, Ky., and paving and sewerage for Cairo, Ill., in 1906 and 1907. He was also Assistant Engineer on hydro-electric projects in California and Colorado in 1907 and 1908.

During the next three years, he was in charge of the Azua Irrigation Project, in Santo Domingo. On this work his duties were manifold and trying, but he completed them to his own satisfaction, and to those who knew him, the meaning of that statement will be clear, as he was his own most meticulous taskmaster. His work consisted of surveys and plans for, and reports on, the watering of 50 000 acres of sugar lands, and a hydro-electric development. After this, he took charge of the location of 55 miles of improved highways for Copiah County, Miss., and the construction of a portion of the work. He then joined the forces of the Uruguay Railway Company, and was placed in charge of railway location and construction, and the building of a reinforced concrete wharf, bridges, buildings, etc.

When visiting one of the camps under his supervision on this work, at Paloma del Sarandi, Mr. Miller found that one of the engineers had died in such a manner that local burial was impossible, and, in view of the refusal of the members of the party to assist him, he himself prepared the body for transportation. Then, with no food from the morning of one day until darkness of the second day, he traveled 60 miles, continuously, through the rainy night, in an ox-cart, secured help at the county seat, bought the ground, obtained authority for the burial, and organized a funeral, in order that the engineer might have the last rites due him, and that his parents, in far off Europe, might know where the body of their son lay.

On two separate occasions, Mr. Miller insisted on accompanying the writer on long trips without explaining his reasons for doing so, but the writer learned months afterwards that he had heard of threats against him for fancied errors in company policy.

From October, 1914, until December, 1916, Mr. Miller was engaged in general consultation practice at his home in Paducah, Ky. In this capacity, he designed additional sewers for Paducah, reported on drainage projects in Kentucky, a hydro-electric plant in Mississippi, and rates for a public utility corporation. He also became well known throughout his adopted State by his earnest efforts, through the press and various organizations, to improve the status of the engineer, to eliminate engineering work from politics, and to further the general interest in good roads. He had built up a good practice, his work being continued during his last absence in Santo Domingo.

On December 9th, 1916, Mr. Miller sailed from New York for Central Romana, a sugar estate of the South Porto Rico Sugar Company, to "study a couple of rivers for hydro-electric and irrigation development", and lived in camp to push the work. This apparently was progressing nicely until the fateful Sunday morning of May 13th, 1917, when his camp was attacked shortly after daylight by a bandit with more than 100 men. The little party was quickly overpowered and led to their death, which took place about an hour afterward. One Spanish helper and a British negro were tied near Mr. Miller and Mr. Hawkins, but only the latter were executed. Mr. Miller explained to the bandit the nature of his work and its non-military character, but was told that "their fault was being Americans." His only plea, that he be allowed to write to his wife, was denied him. Mr. Miller's religious convictions were known only to those who knew him intimately, and it was his marvellous faith that the Divine Will would be done, and his maxim that "one must meet his portion without flinching", which undoubtedly formed the basis for his most extraordinary courage in facing death.

To those who stay behind, the loss is always keen and enduring, but the loss of Mr. Miller is felt with unusual regret. His rapid progress is proof to all of his professional value, and the younger engineers already counted him as a leader. His State will feel the loss of an able, analytical citizen, whose spirit was of the metal that tempers entire communities. The writer was associated with Mr. Miller on various works, and knows how much his friends will miss his counsel, and how much all those who knew him will miss the fine innate sense of justice, coupled with a knowledge of human weaknesses, which made his quietly expressed opinions grow on one like the conception of a fundamental law.

Mr. Miller was married to Miss Ann Bradshaw, of Paducah, Ky., on March 16th, 1911. Their first daughter, Miss Vauban Miller, died and was buried at sea, but their second daughter, Stanley Ann Miller, who was born just six weeks before her father went to Santo Domingo, together with her mother, survives him. He is also survived by his father and mother, Mr. and Mrs. W. R. Miller, his brother, Mr. W. R. Miller, Jr., and his sister, Mrs. W. Molton Evans, all of Baton Rouge, La.

Mr. Miller was a member of New England Water Works Association, the Boston Society of Civil Engineers, and the Sigma Alpha Epsilon Fraternity. He was elected a Junior of the American Society of Civil Engineers on February 4th, 1902, an Associate Member on April 6th, 1909, and a Member on June 24th, 1916.

WILLIAM RIDLEY NEELY, M. Am. Soc. C. E.*

DIED APRIL 11TH, 1916.

William Ridley Neely, the son of Robert Johnson Neely and Elizabeth Norfleet Ridley, was born on August 20th, 1872, in Portsmouth, Va. He was educated at private schools, first at a "Dame's school" in Portsmouth, and then at Norfolk Academy, of Norfolk, Va. He also attended the University of Virginia from 1888 to 1890.

The early years of Robert Johnson Neely, his father, were spent at Newton, Pa., where the old Neely family homestead, built before the Revolution, is now the property of the Daughters of the American Revolution. Early in life he went to Portsmouth, Va., where he was engaged as a lumber manufacturer. He became so identified with the South that he fought with the Confederate Army all through the Civil War. Mr. Neely's mother, Elizabeth Norfleet Ridley, is a collateral descendant of Bishop Ridley who was burned to death for religion's sake in the time of Mary Tudor. She was born and brought up on a plantation near Portsmouth, Va., and was educated in convents in South Carolina and at Richmond, Va. Her father was a well-known landed proprietor of his section, a very fine type of the ante-bellum country gentleman. William Ridley Neely's parentage and traditions were all of the South, and he always took great pride in the development of his home State.

Mr. Neely entered the service of the United States Engineer Department, in the Vicksburg District, in October, 1891, and remained in the employ of the Government for 8 years, being engaged mainly on soundings, precise level work, topographical surveys, and computations, along the Mississippi and tributary rivers. In March, 1899, he was furloughed to take service with the Isthmian Canal surveys in Nicaragua, and remained there until April, 1900, at which time he returned to the Vicksburg District and remained until 1904, in charge of test borings and drafting plans and designing locks, dams, and other structures. In connection with the test borings in the bed of the Ouachita River, several deep borings were made to determine the geological structure of the valley, notably at Catahoula Shoals, Columbia, Rock Row Shoals, Jacks Island, and Newport Landing. The information obtained has been utilized in the later reports on the geology of Louisiana. The plans for the Ouachita locks and dams embraced the designing of foundations in treacherous material, concrete walls subject to earth and water pressure, steel lock gates, and a variety of operating machinery, as well as the solution of many hydraulic problems.

* Memoir prepared by James F. Sanborn, Assoc. M. Am. Soc. C. E.

In May, 1904, Mr. Neely was furloughed to take up engineering work at the West Point Military Academy, where he remained until October, 1906, on work connected with the increase of the water supply for the military reservation there. This involved the location of the pipe line through most difficult country and its actual laying, the length of the line being approximately 6 miles, and the pipe 20 in. in diameter. Mr. Neely did most of the field work connected with this project, and his superior officer considered the service which he rendered very satisfactory. He also assisted in designing the filters which were to be built at West Point.

In October, 1906, Mr. Neely entered the service of the State of New York, as Assistant Engineer in the Engineering Department of the Barge Canal, and continued with that work for more than two years. D. A. Watt, M. Am. Soc. C. E., who was at that time Assistant Engineer, in charge of the Designing Office of the New York State Barge Canal, says:

"He [Mr. Neely] assisted me during that time in preparing the plans for some of the chief sections of the canal, such as the cross-country line just west of Rochester, which comprised two high-lift locks, as well as very heavy cuts and embankments; the line through Phœnix on the Oswego River; and the line through Little Falls. The latter included a lock of 40½ ft. lift, as well as difficult work in carrying the canal through a narrow gorge and along the side of a rock bluff overhanging the Mohawk River. I found Mr. Neely an able man. He was a very hard worker and had originality and accuracy, and I was very sorry to lose his services. He left to accept a more promising position with the State Water Supply Commission."

In the spring of 1908, Mr. Neely was employed as Resident Engineer in charge of two field parties making topographical surveys and maps of the basin of the proposed big Sacandaga Storage Reservoir, near Northville, N. Y., as well as surveys of the storage possibilities at Piseco, Pleasant, and Schroon Lakes. In 1909, he was re-engaged by the State Water Supply Commission, but soon after resigned. Horace Ropes, M. Am. Soc. C. E., speaks of him, as follows: "Mr. Neely was an active and industrious worker, an agreeable person, well liked by those associated with him."

From June, 1909, to April, 1913, Mr. Neely was employed by the Board of Water Supply of the City of New York on the construction of Section 1, Wallkill Division, of the Catskill Aqueduct, at New Paltz, N. Y., of which section he had charge. The work consisted of a standard type concrete aqueduct, in cut and cover, along a strip on the east slope of the Shawangunk Mountains, mainly in rock cut, and a grade tunnel driven toward the north under Bonticou Crag to meet the tunnel driven from the other side of the range. In contrast with the soft-ground problems of his early experience along the lower

Mississippi River, Mr. Neely greatly enjoyed the work and methods used for the hard-rock excavation, timbering, and concrete construction in the tunnel, and the difficulties encountered in open-cut work. In connection with his duties of supervising the construction, he worked out several problems of design for special structures and unusual conditions, and also had the gratification of executing this work. He was a member of the Catskill Aqueduct Association and took great interest in his relations with the engineers he met on that work.

On April 10th, 1913, Mr. Neely resigned to enter the contracting field. He built several miles of the special concrete post and wire fences along the Aqueduct, which occupied him until the spring of 1915. At the time of his death on April 11th, 1916, he was living in Portsmouth, Va.

He was married on February 20th, 1901, to Annie Calvert Jones, of Vicksburg, Miss.

Mr. Neely was a member of the General Alumni Society of the University of Virginia. He was elected a Member of the American Society of Civil Engineers on July 9th, 1906.

HAROLD PARKER, M. Am. Soc. C. E.*

DIED NOVEMBER 29TH, 1916.

Harold Parker, the son of George Alanson and Harriet Newhall Felton Parker, was born in Charlestown, Mass., on June 17th, 1854. He was a direct descendant of Captain Joseph Parker, who settled in Newbury in 1638, and of Nathaniel Felton, who settled in Salem in 1633.

After receiving a preliminary common school education in Philadelphia, Pa., and Lancaster, Mass., Mr. Parker entered Phillips Exeter Academy, from which he was graduated. He then entered Harvard College, where he continued his studies during 1871 and 1872.

Leaving college for a business career, he was first employed in the capacity of Foreman with the Pennsylvania Steel Company. In 1874, he returned to his home town, Lancaster, Mass., and became a member of the civil engineering firm of Parker and Bateman, continuing as such until his death.

Notwithstanding the fact that he was of modest disposition and not of the office-seeking type, Mr. Parker was prominent in the political affairs of Lancaster, and was twice elected to represent his district in the State Legislature. His best years in public service, however, were devoted to the work of building up the highway system of his native State. In 1900 he was appointed by the Governor as a member of the Massachusetts Highway Commission, and on the resignation of William E. McClintock, M. Am. Soc. C. E., in June, 1908, he was made Chairman, which position he held until 1911, when he resigned again to devote his time to other than public office. His ability and tireless industry added to the good repute for gaining progress and results for which this Commission had already become widely known. The revolution in methods of highway transportation and consequent revolution in methods of highway construction was at its height during Mr. Parker's administration as Chairman of the Commission, and many who are continuing the work so ably carried on by him, are indebted to him for his thought and foresight.

Immediately following his resignation as Highway Commissioner, he became Vice-President of a large contracting firm, thus continuing to devote his time to road and pavement work.

In 1913 and 1914, Mr. Parker served the State of New York in an advisory capacity, being designated by Governor Dix as a member of the Advisory Board of the Highway Department.

Being a lover of nature, he spent his leisure in the fields and woods, taking much interest in the forests and natural resources of

* Memoir prepared by A. W. Dean, M. Am. Soc. C. E.

his neighborhood and State, and considering as a pleasure rather than a duty his services as Chairman of the Massachusetts Forestry Commission and of the Wachusett Mountain Reservation Commission.

Indication of Mr. Parker's recognition by others in his chosen field of effort is shown by his selection as President of the Massachusetts Highway Association and of the American Road Builders' Association, in both of which societies he took great interest.

Mr. Parker was a man of the sturdy New England type, of high principles, and a most true friend to those who won his friendship.

He is survived by his widow, Elizabeth B. (Bartol) Parker (to whom he was married in 1884), and by one son and two daughters.

Mr. Parker was elected a Member of the American Society of Civil Engineers on June 7th, 1899.

WILLIAM RODNEY PATTERSON, M. Am. Soc. C. E.*

DIED JULY 19TH, 1916.

William Rodney Patterson was born at Effingham, N. H., on November 4th, 1854.

He was graduated from Dartmouth College in 1876, and, within a few months, was associated with the late Enos M. Barton, of the Western Electric Company. For many years, Mr. Patterson was the Plant Engineer of the Western Electric Company, and had direct charge of the construction and maintenance of all its many buildings, not only in the United States, but also of its various plants in Europe and the Orient.

He was directly responsible for the invention and perfection of the dry-core telephone cable now so generally used throughout the civilized world, as well as of the process of extruding a lead sheath over the cable. He took out more than 100 patents in connection with the development of the telephone cable.

In 1911, Mr. Patterson retired from the Western Electric Company and, until his death, which occurred on July 19th, 1916, after an illness of some months, he was senior member of the firm of Patterson and Davidson, Consulting and Designing Engineers, in Chicago, Ill.

He was a man of quiet reserve, but was nevertheless endowed with an interesting and genial personality, and any one who came in contact with him, in business or socially, became at once his stanch friend. By nature a man of the simplest tastes, he was a great reader and a keen observer. His hobby, during his spare moments, was the preparation of colored lantern slides of architectural and engineering objects, and his library contains many thousands of such slides colored by his own hands. He was a great traveler, and, during the latter years of his life, spent at least one-half his time on foreign shores.

As an executive, Mr. Patterson had few superiors. He had the peculiar natural gift of being able to select his assistants and of having the wise judgment of transferring to them authority and holding them responsible for results, he himself not devoting his valuable time to minute details of work or organization.

While in the employ of the Western Electric Company, he was recognized as its construction genius. He had seen the Company develop from about 25 employees until, at the time of his retirement,

* Memoir prepared by F. E. Davidson, M. Am. Soc. C. E.

they numbered more than 50 000; and in that time the yearly sales had increased from a few thousand to about eighty million dollars.

Engineers will remember Mr. Patterson in connection with the development of the telephone industry, as without doubt its rapid development has been due more directly to the invention and perfection of the dry-core telephone cable than to any other one thing.

Mr. Patterson was elected a Member of the American Society of Civil Engineers on May 4th, 1909.

JOSEPH RAMSEY, Jr., M. Am. Soc. C. E.*

DIED JULY 7TH, 1916.

Joseph Ramsey, Jr., the son of Joseph and Mary (Patterson) Ramsey, was born at Pittsburgh, Pa., on April 17th, 1850. He was educated in the public schools of Pittsburgh, and completed his studies at the Western University of Pennsylvania in 1869.

Mr. Ramsey began his railroad career as a Rodman in the Engineer Corps of the Pittsburgh, Cincinnati and St. Louis Railroad. In 1870 he was made Engineer in charge of the construction of the Dresden Cut-off, at Dresden, Ohio, but resigned to accept the position of Assistant Engineer on location and construction of the Bell's Gap Railroad, and, a year later, was made Assistant Engineer of the Lewiston Division of the Pennsylvania Railroad.

Returning to the Bell's Gap Railroad, in 1872, Mr. Ramsey was made Chief Engineer, and after its completion, in 1873, its Superintendent, in which position he continued until January, 1879, when he entered the service of the Pittsburgh, New Castle and Lake Erie Railroad as Chief Engineer and General Superintendent. He resigned this position in September of that year, to take a similar one with the Pittsburgh Southern Railroad. Mr. Ramsey's unusual abilities were speedily recognized, and he was offered the position of General Manager of the Pittsburgh, Chartiers and Youghiogheny Railroad. While thus engaged, he became General Manager of two other branch roads and the Chartiers Block Coal Company.

From 1883 to 1890 Mr. Ramsey served as Chief Engineer of the Cincinnati, Hamilton and Dayton Railroad, resigning to become Assistant to the President of the Cleveland, Cincinnati, Chicago and St. Louis Railroad, which post he retained until 1892. From 1890 to 1895 he was President of the Peoria and Pekin Union Railway and, from 1891 to 1893, Vice-President of the Cincinnati, Wabash and Michigan Railroad, having charge of the Operating and Traffic Departments of both these companies, while holding the Presidency of the Findlay Belt Railway. In June, 1891, he was made General Manager of the Cleveland, Cincinnati, Chicago and St. Louis Railway, and, in 1892, was elected General Manager and Vice-President of the Dayton Union Railroad. In April, 1893, Mr. Ramsey accepted the position of General Manager of the Terminal Railroad Association of St. Louis, which position he held until December 1st, 1895, when he was made Vice-President and General Manager of the Wabash Railroad Company. He was made President of the entire Wabash System in 1901, a position which he filled for five years with signal success.

* Memoir prepared by John P. Ramsey, Esq.

Mr. Ramsey was also President of the Wheeling and Lake Erie Railroad and the Wabash-Pittsburgh Terminal Railroad from 1901 to 1905; the Ann Arbor Railroad from 1902 to 1906; and the Western Maryland Railroad and West Virginia Central Railroad from 1903 to 1905. He also served as President of the Pittsburgh and Chicago Railroad, the Lorain and Ashland, and the Ashland and Western Railways. In 1913, Mr. Ramsey became President and General Manager of the Lorain, Ashland and Southern Railroad, which he had built. While President of the Wabash Railroad he was sent to the Paris Exposition of 1900 as Railroad Commissioner from the United States.

Mr. Ramsey was a Director of the Louisiana Purchase Exposition, at St. Louis, Mo., and Vice-President of its Committees on Electricity and Electrical Appliances and Transportation. He was also connected with several companies as Director and Committeeman. He was a member of the Commercial and Noonday Clubs, of St. Louis, Mo., the Duquesne Club, of Pittsburgh, Pa., and the Toledo Club, of Toledo, Ohio.

Mr. Ramsey was married on April 8th, 1873, to Laura, daughter of James E. Palmer, of Zanesville, Ohio, who, with two sons, James Palmer and John Patterson, and three daughters, Mrs. Helen R. Fowler, Miss Jane M. Ramsey, and Mrs. Mary R. McIntyre, survives him. His death occurred at East Orange, N. J., on July 7th, 1916.

Mr. Ramsey was elected a Member of the American Society of Civil Engineers on May 1st, 1889, and served as a Director from 1900 to 1902, inclusive.

THOMAS FRANKLIN RICHARDSON, M. Am. Soc. C. E.*

DIED DECEMBER 26TH, 1915.

Thomas Franklin Richardson was born at Woburn, Mass., on February 10th, 1855. He was of Colonial ancestry, having been descended from Samuel Richardson who came to this country about 1630 from the south of England and settled in what is now Winchester, Mass.

Mr. Richardson was graduated in 1872 from the Boston English High School, and began his career as a Civil Engineer in May, 1873, as Rodman on the location and construction of the aqueduct for the Sudbury Water-Works, for the City of Boston. When the work was finished in December, 1878, he had been promoted to the position of Instrumentman.

From December, 1878, to October, 1879, he was employed as Assistant Engineer for the City of Chelsea, Mass., in charge of the construction of the main trunk sewer for that place.

In January, 1880, Mr. Richardson went West as Topographer on surveys for the location of the Atlantic and Pacific Railroad (now part of the Santa Fé System), and in seven months was made Division Engineer, which position he held until June, 1882. As Division Engineer, he had charge of the construction of about 25 miles of railroad in New Mexico and Arizona and was also active in the management of that portion of the road. His work here included the construction of the Cañon Diablo and the Padre Cañon Bridges in Arizona, the former of which was a notable piece of engineering for that time, being a steel trestle about 225 ft. high and 600 ft. long. Labor conditions were extremely bad in this country, and water for construction purposes had to be hauled from 25 to 30 miles, largely by teams, thus making the work very difficult.

In October, 1882, Mr. Richardson joined the Engineering Corps of the Mexican Central Railway Company as Assistant Engineer. In this capacity he had charge of the construction of the Encarnacion Bridge, 175 ft. high and 1 300 ft. long. At that time this bridge was considered to be the most important piece of bridge work undertaken in Mexico. He remained with this Company until July, 1885, serving for about a year as Bridge Engineer on the southern half of the road and, for another year, as Resident Engineer on the northern 600 miles of the same road, designing and constructing a great many of the bridges.

In September, 1885, Mr. Richardson was appointed Division Engineer on the construction of the Chicago, Burlington and Northern

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

Railroad in Wisconsin, in charge of timber trestle work over the Wisconsin River and also of the heavy grading work. In July, 1886, he entered the employ of the Colorado Fuel Company, making railroad surveys, designing structures, and making estimates for the development of that Company's coal properties in the mountains between Glenwood Springs and Aspen, Colo. He also located a number of railroad lines in this region with grades as high as 5%, using switchbacks on many of the lines. He remained with the Colorado Fuel Company until May, 1887, when he was made Division Engineer on the construction of the Atchison, Topeka and Santa Fé Railroad. In this capacity he had charge of the Division Yard at Chillicothe and the heavy work near the Illinois River. For the greater part of the last year (1888) he served as Resident Engineer in charge of all new work in the State of Illinois.

From January to April, 1889, Mr. Richardson was engaged on the location of a line in the San Luis Valley, from Valley Grove to Alamaso, for the Denver and Rio Grande Railroad, and, from April, 1889, to January, 1892, he was Chief Engineer on the location and construction of the Manitou and Pike's Peak Railroad. This road has a maximum grade of 25 ft. per 100, with a maximum curvature of 16°, is 9 miles long, and extends from an elevation of about 6 000 ft. to one of 14 100 ft. above sea level, about 3½ miles of it being above the timber line. Mr. Richardson designed all the structures and all the appliances for laying the Abt rack rail which was used on this line.

In February, 1892, he went to Chicago, Ill., where he entered the service of the Sanitary District as Assistant Engineer, having charge of the construction of several miles of the Lemont portion of the main channel, and from April to August, 1893, he served as Engineer in charge of the construction of the 68th Street Tunnel (one of the water tunnels built of brick through clay and silt 4 miles under Lake Michigan) for the City of Chicago.

In August, 1893, Mr. Richardson returned to Massachusetts where he entered the service of the State Board of Health and, until June, 1895, had charge of surveys for all the reservoirs and aqueducts in connection with the investigations for a water supply for the Metropolitan District. He made the preliminary locations, designs, and estimates of cost, for the location of the Wachusett Aqueduct; the Wachusett Reservoir and Dam, including all appurtenances thereto; a reservoir on Ware River, together with a tunnel 8.7 miles long connecting it with the Wachusett Reservoir; a reservoir on Swift River, including a tunnel 27.6 miles long, also connecting this reservoir with the Wachusett Reservoir; and the Weston Aqueduct, as well as many other sources of supply.

From July, 1895, to January, 1906, Mr. Richardson was employed as Engineer of the Dam and Aqueduct Department of the Metropolitan

Water-Works, in charge of the construction of the Wachusett Reservoir, 12 miles long, which work included a tunnel 2 miles long and a masonry arch bridge over the Valley of the Assabet River. He also had charge of the construction of the sewage filtering system for Clinton, Mass., including a power-house and 25 acres of filter beds. Until May, 1906, he had charge of studies for the location and design of the North Dike and the land surveys for the Wachusett Reservoir. This work included the relocation of the Central Massachusetts Railroad from Berlin Junction to the North Dike, with a steel viaduct about 135 ft. high and 1 000 ft. long, across the Nashua River below the dam. Mr. Richardson also made the final location for the Weston Aqueduct and was in charge of the construction work in connection with the Wachusett Dam, as well as serving as Engineer of the Reservoir Department in 1905.

In January, 1906, Mr. Richardson entered the employ of the J. G. White Company, Incorporated, as Construction Superintendent in charge at the Laguna Dam near Yuma, Ariz., for the United States Reclamation Service.

In March of the same year, he returned to the Metropolitan Water-Works of Boston, Mass., as Engineer of the Dam and Reservoir Department, which position he held until July, when he was appointed Resident Manager in charge of the construction of the plant of the Rockingham Power Company on the Peedee River at Hamlet, N. C., where he remained until July, 1907.

In September, 1907, Mr. Richardson again joined the forces of the J. G. White Company, Incorporated, and was placed in charge of the La Crosse water-power development at Hatfield, Wis. In December, 1907, he returned to New York City, and on January 1st, 1908, was appointed General Superintendent of Construction in charge of contract work for the New York office. In this capacity, he had charge of various large hydro-electric works, such as the La Crosse Power Company's development, at Hatfield, Wis.; the Connecticut River Power Company's development near Brattleboro, Vt.; the Central Georgia Power Company's development at Jackson, Ga.; the Idaho-Oregon Light and Power Company's development at Copperfield, Ore.; the Minnesota-Ontario Power Company's development at International Falls, Minn., as well as the Idaho Irrigation development in the vicinity of Richfield, Idaho. Mr. Richardson continued as General Superintendent of Construction until September 1st, 1909, when he was made Chief Civil Engineer of the Company. While in this position, he made numerous investigations, studies, and cost estimates for power developments and also acted as Consulting Expert in engineering matters for the Company. During this time he was also

engaged as Consulting Engineer in connection with the Fellsmere Farms Company's work of reclaiming swamp lands in Florida.

When the Engineering Department of the J. G. White Company, Incorporated, was taken over by its subsidiary, The J. G. White Engineering Corporation, January 1st, 1913, Mr. Richardson became Civil Engineer for the latter, which position he retained until August 1st, 1914, when he was obliged to resign on account of failing health. He continued, however, to engage in consulting work until a short time before his death which occurred at his home at Rutherford, N. J., on December 26th, 1915.

Mr. Richardson was engaged for more than 40 years in all kinds of engineering work, including the construction of railroads, water supply, irrigation, drainage, and hydro-electric projects. His work extended over all parts of the United States, which fact made him widely known as a capable engineer, an energetic executive, and a faithful and honest man.

On October 4th, 1888, Mr. Richardson was married to Miss Nellie Symonds who, with three sons, survives him.

He was a member of the Boston Society of Civil Engineers, the New England Water Works Association, and the Engineers' Club of New York City. He was also a Knight Templar and a Mystic Shriner.

Mr. Richardson was elected a Member of the American Society of Civil Engineers on November 4th, 1885.

ROBERT MAITLAND ROY, M. Am. Soc. C. E.*

DIED JUNE 27TH, 1916.

Robert Maitland Roy, the son of Robert Maitland and Maria Roy, was born at Stirling, Ont., Canada, on November 27th, 1869. He was educated in the public and high schools of Belleville, Ont., and was graduated from Ontario Commercial College. He also spent a year or more in the study of commercial and contract law, and took a special private course in mathematics.

In June, 1886, Mr. Roy entered the employ of the Grand Trunk Railway, serving, until October, 1888, in the Traffic and Engineering Departments.

From October, 1888, to February, 1892, he was engaged as Assistant Mechanical Engineer with the G. and J. Brown Manufacturing Company, of Belleville, Ont., inspecting Government and railway supplies, contractors' plant for public works, railway, mining, and other contracts, as well as structural work of various kinds. Mr. Roy was also engaged during this time on Government surveys of the Belleville Harbor and River protection works, on extensions to the Belleville Water-Works, and on new sewerage and pumping plants for the Government Institution for the Deaf and Dumb at Belleville.

From February, 1892, to January, 1898, Mr. Roy was employed with the Central Bridge and Engineering Company, of Peterborough, Ont., as Assistant and Contracting Engineer for railway and highway bridges and general structural work. He was also engaged during this time on surveys of the Trent Canal and other works.

In January, 1898, Mr. Roy entered the employ of the Hamilton Bridge Works Company, Limited, of Hamilton, Ont., serving as Highway Bridge Engineer from 1898 to 1908, as Manager, from 1908 to 1916, and as Director from 1913 to 1916, which latter positions he held at the time of his death, on June 27th, 1916.

Mr. Roy was a Member of the Canadian Society of Civil Engineers, the Hamilton Board of Trade, and the Canadian Manufacturers Association, and had served as an Alderman of Hamilton, Ont., from 1913 to 1916. He was also a member of the Hamilton, Twentieth Century, Canadian, and Hamilton Automobile Clubs, the I. O. O. F., the A. F. and A. M., and of the Church of England.

On April 19th, 1894, Mr. Roy was married to Mary Ann Wragg, daughter of Thomas B. Wragg, of Belleville, Ont., who, with four sons, survives him.

Mr. Roy was elected an Associate Member of the American Society of Civil Engineers on October 3d, 1900, and a Member on March 5th, 1907.

* Memoir prepared by the Secretary from information supplied by J. A. Spittle, Esq.

LEONARD WARREN RUNDLETT, M. Am. Soc. C. E.*

DIED OCTOBER 13TH, 1916.

Leonard Warren Rundlett was born in Alna, Lincoln County, Me., on September 21st, 1846. During boyhood he lived in Brunswick, Me. While he was very young his father died, after which he lived with his widowed mother and only sister. He attended school at Brunswick, and was graduated from Bowdoin College in 1868, afterward taking a post-graduate course in engineering.

Two years after graduation he went to St. Paul, Minn., where he joined the Engineer Corps of the St. Paul and Pacific Railroad Company (now the Great Northern Railway), and was engaged for two years in railroad construction work in Minnesota.

In 1872 Mr. Rundlett entered the employ of the City Engineer of St. Paul. He remained in this office, succeeding to that position nine years later. Resigning from that office in 1883, he devoted two years to planning and constructing the St. Paul Water-Works. He then resumed the position of City Engineer and remained in charge of the engineering work of the city, with the exception of one term, until 1911. During this time the city had increased from a frontier town of 25 000 people to a city of 250 000. Its public works, bridges, streets, sewers, water-works, and public buildings, costing many millions, had been planned and executed under his supervision. The administration of the Engineering Department had occupied practically all his professional life, as he had been connected with it for 38 years; during this time the city government was controlled by parties of different political views, but, in the words of the leading paper of the city after his death:

"Through them all L. W. Rundlett was recognized as a competent engineer and a personally honest man. He came through all without a taint upon his personal honesty."

The Commercial Club of the city, of which he was an active member for many years, in memorial resolutions states:

"During many years of work as a public official of this city he exemplified the highest type of official service, marked by ability, integrity, and humanity; and was in all things above the temptations of office, power, or place; caring not for public or personal honors so much as he cared for the approval of his own conscience and the merited affection of his fellow-men."

During the term he was not City Engineer, Mr. Rundlett was in charge of important hydraulic development on the Apple River, Wisconsin.

* Memoir prepared by George L. Wilson, M. Am. Soc. C. E.

In 1913 and 1914 he was Commissioner of Public Works for the City of Moose Jaw, Saskatchewan, Canada. After this, he opened an office as Consulting Engineer in St. Paul. His health had been poor for some months; he had been suffering from heart trouble, but finally, on October 13th, the end came suddenly at his home.

He was married to Miss Mary Atwater Barry, of Milwaukee, Wis., on October 27th, 1881. Miss Barry was the daughter of Capt. Garrett Barry, a graduate of West Point, and Mary Atwater, of Wallingford, Conn. Mrs. Rundlett and one daughter, Mrs. Garritta (Rundlett) Edgerton, survive him.

Mr. Rundlett was elected a Member of the American Society of Civil Engineers on September 5th, 1883. He served as a Director of the Society in 1911-13.

FRANK EDSON SHEDD, M. Am. Soc. C. E.*

DIED SEPTEMBER 22D, 1916.

Frank Edson Shedd was born in Sharon, N. H., on July 18th, 1856. He attended the Conant High School of East Jaffrey, N. H., and entered Dartmouth College, from which he was graduated in the Class of 1880.

After a year of teaching, as Principal of a high school, Mr. Shedd entered the service of the United States Coast and Geodetic Survey, where he remained for a year, his work being on the charting of the coast of Maine. In 1882, he left the service of the Government to take up civil engineering in Lowell, Mass.

In 1886, Mr. Shedd had charge of the erection of the Washington Mills, at Lawrence, Mass., at that time one of the largest mill construction propositions which had ever been undertaken. These mills are now owned by the American Woolen Company.

In April, 1887, he became a member of the staff of Lockwood, Greene and Company, the engineering firm which had designed the Washington Mills, and two years later was made First Assistant to Mr. Stephen Greene, then the sole member of the firm. From that time until his death, Mr. Shedd maintained an intimate connection with that organization.

On January 1st, 1901, on the incorporation of Lockwood, Greene and Company, Mr. Shedd became a Director and the Vice-President of the firm, and held both these positions until his death. He was a Civil Engineer of high standing, and had designed many large mills and hydraulic plants in various parts of the United States and Canada, having been considered one of the leading authorities in this country on hydraulic developments.

Mr. Shedd was a man of varied interests; a member of the Boston Society of Civil Engineers and of the American Society of Mechanical Engineers, he was also a member of St. John's Lodge, A. F. and A. M., of Boston, a Companion in the Mount Vernon Royal Arch Chapter, and a member of the Second Parish Congregational Church, of Dorchester, Mass.

Mr. Shedd was also a member of the New Hampshire Historical Society and a life member of the New England Historic Genealogical Society. He was the founder, as well as the Secretary and Treasurer, of the Shedd Family Association, and designed the handsome monument—erected at Shedd's Neck, in Quincy, Mass., three weeks prior to his death—by the Shedd Association, in honor of the first ancestor of

* Memoir prepared by Mr. Frank W. Reynolds, of Lockwood, Greene and Company, Boston, Mass.

the family in America. Having been for many years much interested in genealogical research, he had collected many valuable data regarding the Shedd descendants in America, and was making plans, when taken sick, looking toward the early publication of a genealogy of the family.

Mr. Shedd was a thorough, painstaking engineer, of retentive memory, wise judgment, and tireless industry; a modest unobtrusive gentleman of sterling character. One of his friends says of him:

"He was a high-minded citizen and represented the highest ideals of human life; he rendered a large service to his fellow-men; he was an honor to his Profession and has left behind him a name which ought to be an inspiration and help to us all for higher and better things."

During his illness, which covered the last six months of his life, Mr. Shedd suffered much, but bore his sufferings with great fortitude, and attended to many affairs up to the very last. He died at his home in Dorchester, Mass., on September 22d, 1916, leaving a widow and one son.

Mr. Shedd was elected a Member of the American Society of Civil Engineers on February 6th, 1907.

DAVID SIMSON, M. Am. Soc. C. E.*

DIED DECEMBER 16TH, 1916.

David Simson was born at Bedrule House, Roxburghshire, Scotland, on November 9th, 1861. He was educated at St. Andrew's and Edinburgh University, and from September, 1877, to June, 1879, served as Apprentice Mechanical Engineer in the shops of Messrs. Douglas and Grant, at Kirkcaldy, Scotland, where he was engaged on the construction of large stationary engines, boilers, sugar and paper machinery, etc. From February, 1880, to January, 1882, he also worked as an Apprentice to Messrs. Carfrae and Belfrage, Land Surveyors, of Edinburgh, Scotland, and was engaged in surveying, the construction of roads, sewers, etc.

Having served his apprenticeship, Mr. Simson was employed, from January, 1882, to July, 1884, by Messrs. J. Waddell and Son, Railway Contractors, of Edinburgh, as Contractor's Engineer in charge of the construction of the eastern half of the Edinburgh Suburban Railway. This work involved the deviation of streets, sewers, etc., and the crossing of the new railway over and under existing railways and canals.

From August to November, 1884, Mr. Simson traveled over the greater part of the United States and Canada, in order to study American methods of railroad construction. On his return to his home, he was engaged, from January to June, 1885, by the creditors of Messrs. L. and K. Macdonald, Contractors, to finish the construction of the Killin Railway, in Perthshire, Scotland. One of the most important parts of this work was the construction of a viaduct over the River Dochart. This viaduct consisted of five skew spans of about 50 ft. each, the arches being of concrete. This is the first instance in which concrete was used for arches of this magnitude in railway construction in Great Britain.

In June, 1885, Mr. Simson entered the employ of John Strain, Civil Engineer, and was engaged in making surveys and preparing drawings for the various railway construction projects on which the firm was working. He also assisted Mr. Strain in giving evidence before Parliamentary Commissions in London, and in 1887-88, served as Resident Engineer on the construction of the Kilbirnie Branch of the Lanarkshire and Ayrshire Railway, for which he had previously made the surveys and drawings.

In September, 1888, Mr. Simson resigned his position with Mr. Strain, and went to South America where he was appointed Chief Assistant Resident Engineer on the Mountain Division of the Buenos Aires and Valparaiso Transandine Railway from Mendoza. This Division covered 100 miles of extremely difficult mountain railway

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

construction, especially in connection with the gorge of the Mendoza River in which the roadbed had to be blasted from the sides of the precipice. Mr. Simson remained in this position until November, 1891, at which time the line was constructed and open as far as Rio Blanco, and work on the Summit Tunnel had been commenced.

He then returned to Scotland, but, in October, 1892, he was appointed Chief Engineer of the Western Railway of Havana, in Cuba, which position he held until June, 1896. During his incumbency, all the old timber trestles along the line of this road were replaced by steel structures, and the railroad was extended 10 miles to Pinar del Rio, into the heart of the best tobacco district on the island.

In November, 1896, Mr. Simson entered the service of the Buenos Aires Western Railway Company as Chief Engineer, with headquarters at Buenos Aires. In September, 1897, he was appointed Acting Manager, and in September, 1898, General Manager of the Company, which position he held until December, 1906. On his retirement, the employes of the Railway Company presented him with a silver model of a locomotive in token of their affection and respect.

From January to March, 1907, Mr. Simson was engaged in Chile and Bolivia, in making a report on the affairs of the Antofagasta and Bolivia Railway. In April of that year, he retired from the active practice of engineering and returned to England to make his home.

Subsequently, he was elected a member of the Board of Directors of the Buenos Aires Western, the Antofagasta and Bolivia, and the Great Western of Brazil Railways, but he was obliged to retire from the latter two, in 1912 and 1913, respectively, on account of pressure of other work. He had also been elected, in November, 1907, a Director of the Buenos Aires Great Southern Railway Company, and was made Chairman of the Board in September, 1910. He was also a Director of the Buenos Aires Southern Dock Company and of the London and River Plate Bank.

At the time of his death, which occurred suddenly by heart failure at his home at Ickleford Manor, Hitchin, Herts, Mr. Simson was actively engaged in war relief work in his district.

He was a member of the Institution of Civil Engineers of Great Britain, and a "Caballero" of the Second Class of the Spanish Order of Military Merit, having been decorated for services rendered the Spanish Government in conducting armored trains and repairing the Western Railway of Havana under fire during the Cuban Rebellion of 1896.

He was widely versed in South American affairs, and his death will be deeply felt by the Anglo-Argentine Colony of which he was one of the best known and most valued members. He is survived by his widow and one son.

Mr. Simson was elected a Member of the American Society of Civil Engineers on January 8th, 1902.

FRANK OSCAR SINCLAIR, M. Am. Soc. C. E.*

DIED NOVEMBER 15TH, 1916.

Frank Oscar Sinclair was born at Burlington, Vt., on September 7th, 1860. He received his technical education at the University of Vermont, from which he was graduated in the Class of 1882.

During the summers of 1881 and 1882 he was employed as Assistant Engineer on the location and construction of the Canada-Atlantic Railway. In May, 1883, Mr. Sinclair went West and was engaged until July, 1884, as Assistant City Engineer of Leavenworth, Kans., in charge, under the late G. W. Pearsons, M. Am. Soc. C. E., as Consulting Engineer, of the construction of a sewer system for that city.

From July, 1884, to October, 1892, he was engaged on railroad work in the West and South, as follows: July, 1884, to January, 1885, Assistant Engineer with the Missouri Pacific Railway Company, with headquarters at Atchison, Kans.; July, 1885, to July, 1887, Assistant and Division Engineer with the Chicago, Rock Island, and Pacific Railway Company, in charge of part of location and construction on lines west of the Missouri River; September, 1887, to July, 1890, Principal Assistant Engineer of the Knoxville Southern Railway; July to November, 1890, on location for the West Virginia and Pittsburgh Railroad Company in West Virginia; August, 1891, to October, 1892, Chief Engineer for the Ducktown (Tenn.) Mineral Railway Company and the Ducktown Sulphur, Copper, and Iron Company, constructing a narrow-gauge railway, erecting a crushing plant, smelting sheds, roasting furnaces, etc.

Mr. Sinclair then returned to Burlington, Vt., where he opened an office and engaged in private practice as a Consulting Engineer. He served as Chief Engineer on the construction of the Burlington Traction Company's lines, the water-power plant for Vergennes, and the Bolton Falls Dam. He was also engaged, from June, 1896, to August, 1900, as Contracting Engineer for the Pittsburgh Bridge Company in Vermont.

In 1904, Mr. Sinclair was appointed City Engineer of Burlington, Vt., and held that office until his death. He also served as a member of the Board of Aldermen from Ward 1, from 1899 to 1903; Superintendent of the Water Department from 1905 to 1909; and Member of the Board of Street Commissioners from 1913 to 1916, serving as Chairman in 1913 and 1914.

In 1910, Mr. Sinclair was appointed Consulting Engineer of the Public Service Commission of Vermont, which position he held at

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

the time of his death which occurred on November 15th, 1916, following an operation. He is survived by his widow and three children, and by two brothers.

Mr. Sinclair was a man of the conservative type. He had many times proved himself capable of grasping large problems and of working them out successfully. He had established a reputation as a careful and accurate engineer, in recognition of which he had filled many positions of trust, among which was a recent appointment by the Secretary of the Navy as Chairman of the State Directors and Associate Members of the Naval Construction Board of Vermont. His sudden death was a distinct shock to the people of Burlington, which city he had served worthily in so many capacities, and his loss will be deeply felt by all who knew him.

He was a Past-President of the Vermont Society of Engineers, a member of Hamilton Lodge, I. O. O. F., the Algonquin Club, and a charter member of Vermont Alpha of Phi Delta Theta. He was also a member of the Official Board of the Methodist Church, and had been a teacher in the Sunday School for many years.

Mr. Sinclair was elected a Member of the American Society of Civil Engineers on November 6th, 1901.

DAVID WENDEL SPENCE, M. Am. Soc. C. E.*

DIED JUNE 28TH, 1917.

On September 22d, 1868, David Wendel Spence, the son of the late Joseph and Margaretta (Wendel) Spence, was born at Austin, Tex. His early education was obtained at private schools in Austin, and, for four years, he was a member of the classes in the late Professor Bickler's Academy. In June, 1889, he received his B. Sc. degree from the then young University of Texas, his work as a student having been in the Civil Engineering course.

During the summer of 1889, Mr. Spence was a member of the geological field party of the late Dr. Theodore B. Comstock, then Geologist in charge of the investigation of the Central Mineral District of Texas, on the Texas State Geological Survey. In September, 1889, he entered the University of Michigan where he pursued advanced work in civil engineering under the late Charles E. Greene, M. Am. Soc. C. E., then Professor of Civil Engineering in that institution, and spent one year in resident study. In 1891, after having had one year's active practice in his profession, at Denver, Colo., he received his C. E. degree from the University of Michigan.

Mr. Spence's year in Denver was spent in the office of the Lane Bridge and Iron Works, the factory of which company was in Chicago, Ill. Later, he returned to Chicago, and was Chief Draftsman of the South Halsted Street Iron Works until September, 1892, when he resigned to return to Texas to accept a position in the Agricultural and Mechanical College of Texas, with which institution he maintained continuous connection until his death. During his twenty-five years of service at the College, he occupied, successively, the following positions: 1892 to 1898, Assistant Professor of Civil Engineering and Physics, and of Drawing; 1898 to 1899, Associate Professor of Civil Engineering and Physics, and Drawing; 1899 to 1904, Professor of Physics; 1904 to 1908, Associate Professor of Civil Engineering; 1908 to 1913, Professor of Structural Engineering; and, 1913 to 1917, Dean of the School of Engineering, and Professor of Civil Engineering.

Dean Spence organized the Texas Engineering Experiment Station, at the Agricultural and Mechanical College, and was its Director from its inception until his death. He also rendered additional valuable service to the College along several lines of physical development. From 1907 to 1911, he was in charge of repairs to buildings, and of the maintenance and extension of the water supply and sewer systems of that institution. He was also Supervisor of Construction of the $100 000 mess hall, built at the College in 1913. From 1912 until

* Memoir prepared by J. C. Nagle, M. Am. Soc. C. E.

the time of his death, Dean Spence was Supervising Engineer for all new construction work at the Prairie View, Tex., Normal and Industrial College (for negroes), over which the Board of Directors of the Agricultural and Mechanical College has jurisdiction. From 1911 until his death, he had complete charge of the repairs to buildings, and of water-works and sewer extensions, at Prairie View.

During his vacations, Dean Spence occupied various positions, among which the following may be mentioned: 1894, Assistant Engineer, Brazos and Burleson Railway Company; 1895 and 1896, Engineer, Brazos River Channel and Dock Company, Velasco, Tex.; 1899, Draftsman, Union Bridge Company, Athens, Pa.; 1900, Assistant Engineer, Houston, East and West Texas Railroad Company; 1901 Draftsman, Columbia Bridge Company, Carnegie, Pa.; 1903, Assistant Locating Engineer, Gulf, West Texas and Pacific Railroad Company; and 1905, Draftsman, Penn Bridge Company, Beaver Falls, Pa.

Dean Spence also did considerable private work as Consulting Engineer, especially on highway bridges.

Among his former students are numbered many prominent engineers, not only of Texas, but of other States and of foreign countries, every one of whom bears him in affectionate remembrance, and who, together with a host of other friends, deeply mourn his untimely end. Zeal for his work, and love for his institution, caused him for years to overtax himself, and to disregard the warnings of failing health. Almost up to the very hour of his death, he was busy planning betterments in his college courses and improvements in the conduct of his Department. Long will the College miss his wise counsel and energetic efforts in its behalf.

In June, 1893, Mr. Spence was married to Miss Lucy Reese, daughter of the late distinguished Judge T. S. Reese, at Hempstead, Tex., who, with one son (who also is a civil engineer), and two daughters, survives him.

Dean Spence was elected a Member of the American Society of Civil Engineers on October 1st, 1913.

HENRY GORDON STOTT, M. Am. Soc. C. E.*

DIED JANUARY 15TH, 1917.

Henry Gordon Stott was a native of the Orkney Islands, Scotland, where he was born on May 13th, 1866, the son of the Rev. David and Elizabeth Jane (Dibblee) Scott. After a thorough grounding in the fundamentals, by his father and elementary school instructors, he was enrolled as a student at the Watson Collegiate School, Edinburgh. On leaving this institution he entered the College of Arts and Sciences at Glasgow, and began a course in mechanical engineering and electricity, being graduated in 1885. In the year previous he had entered the employ of the Electric Illuminating Company, of Glasgow. Shortly after his graduation he was made Assistant Electrician on board the Steamship *Minia*, belonging to the Anglo-American Telegraph Company. The next 4½ years saw him engaged with those duties, during the course of which he saw much service in connection with repairs to the cable lines of that company. During this period he undertook a number of experiments that resulted in the introduction of improved methods of handling cable repairs. He was also identified with the "duplexing" of the United States Cable Company's main cable (2 750 knots), the longest duplex cable in the world.

In 1889 Mr. Stott was made Assistant Engineer of the Brush Electric Engineering Company's plant at Bournemouth, England. In the following year he accepted a position with Hammond and Company as Assistant Engineer in the construction of an underground cable and power plant at Madrid, Spain. He remained there until 1891, coming to the United States in that year to construct an underground cable and conduit system for the Buffalo Light and Power Company (now the Buffalo General Electric Company). This work was completed with a degree of success that reflected very great credit on Mr. Stott. As a result he was named Engineer of the company, and during the next 10 years was one of the most active figures in the industrial progress of Buffalo. During this period he designed and executed some notable construction work, including a power-plant on Wilkeson Street, Buffalo.

His efforts attracted wide attention, and in 1901 he was appointed Superintendent of Motive Power of the Interborough Rapid Transit Company, New York City, a position which he filled with signal success. At the time he took up these duties the Interborough had not yet been organized, the company having the title of the Manhattan Railway Company. The post to which Mr. Stott was called had just

*Memoir prepared by W. S. Finlay, Jr., Esq.

been created, and it devolved upon him to organize the operating force, in connection with which he completed the 74th Street power-plant of the company, and various sub-stations and transmission lines.

When the Manhattan System was amalgamated with the Interborough, in 1904, Mr. Stott was invited to retain his office with the new corporation. He accepted, and immediately took over supervision of the construction of the power-plant on 59th Street. Since that time he had been constantly in charge of the design, construction, and operation of the power generating stations and the distributing system of the Interborough, which comprehends both the subway, elevated, and surface lines of New York City.

The plans for the electric power system of the new subway lines were developed under his supervision, and the work has progressed so far and bears so strongly the stamp of his work that, when completed, it will be a monument to him.

Mr. Stott was a firm believer in co-operation among engineers, through the agency of engineering societies. He was elected President of the American Institute of Electrical Engineers for the term 1907-1908, Vice-President of the American Society of Mechanical Engineers for the term 1912-1914, Director of the American Society of Civil Engineers in 1911, and was Vice-President and Trustee of the United Engineering Society at the time of his death. Up to the last, Mr. Stott was a recognized power in the American Institute of Electrical Engineers, and was a member of the Standards Committee, the Committee on Development of Water-Power, the United States National Committee of the International Electrotechnical Commission, the Power Stations Committee, the Public Policy Committee, the Edison Medal Committee, the Committee on Economics of Electric Service, and was one of the Institute's representatives on the Joint Committee on the Metric System, of which he was an ardent advocate.

As a result of his unusually wide experience and extended research, Mr. Stott was called on often to contribute papers to the various engineering societies. He was especially well known for his minute analysis of enginering problems. Among the many papers written by him on this subject are "The Conversion and Distribution of Received Currents", "Power Plant Economics", "Notes on the Cost of Power", "Steam Pipe Covering and Its Relation to Station Economy", "Tests of a 15 000-Kilowatt Steam Engine Turbine Unit", "Power Plant Design and Operation" (a series), etc.

Mr. Stott was a remarkable figure in the engineering world, because he was in the front rank of both electrical and mechanical engineers, because, in both branches of the art, he was a master of theory and practice, and because, with these technical qualifications, he combined a rare executive ability, a power of inspiring the confidence of his

employees, and of bringing out the best that was in the men who worked for him.

Mr. Stott's activities were not confined to engineering matters. He early became a citizen of the United States and served for 5 years in the 74th Regiment of the National Guard of New York State.

He was also an active member of the Protestant Episcopal Church, being a communicant of St. Paul's Church, of New Rochelle, in the affairs of which he was deeply interested.

Mr. Stott was married on July 22d, 1894, to Miss Anna Mitchell, of Belfast, Ireland, who, with their two children, a son and a daughter, survives him. He died at his home, in New Rochelle, N. Y., on January 15th, 1917, after an illness of many months.

Mr. Stott was elected a Member of the American Society of Civil Engineers on July 1st, 1908.

SLEDGE TATUM, M. Am. Soc. C. E.*

DIED JANUARY 18TH, 1916.

Sledge Tatum, the son of Seth and Sarah Elizabeth Tatum, was born on July 10th, 1870, at LaGrange, Ga. He received his education at the LaGrange High School and from private instructors.

He began his professional career in 1886 in the Engineering Department of the Macon and Birmingham Railroad, and, later, was engaged in surveying and engineering work in Fulton and Troup Counties, Georgia.

In 1894 he was elected a member of the Georgia Legislature to represent Troup County.

In May, 1895, Mr. Tatum was appointed Surveyor in the United States Geological Survey, and spent several years surveying land lines in Indian Territory. In 1899, he was appointed Topographer, and carried on triangulation in various States. In 1903, he surveyed forest boundaries in Washington and Idaho, and the following year executed triangulation along the International Boundary.

On June 10th, 1905, he was transferred from the Department of the Interior for service with the Department of Engineering of the Isthmian Canal Commission. He began work in the Canal Zone as Instrumentman on the Chagres River surveys, and advanced rapidly through the different grades, at one time having charge of all the survey parties in the field, both on the Chagres River Division and the Canal Zone boundary. On November 1st, 1908, Mr. Tatum was made Superintendent of Construction and was employed on the building of the Gatun Dam under Gen. William L. Sibert, M. Am. Soc. C. E., Division Engineer. He had charge of the surveys, the excavation at the spillway, and the driving and filling of all trestles. He resigned on February 8th, 1909, to accept a transfer to the United States Geological Survey.

On his return to the Survey, Mr. Tatum was assigned to special investigations and, on June 1st, 1910, was appointed Geographer in charge of the Rocky Mountain Division, comprising North and South Dakota, Kansas, Nebraska, Oklahoma, Montana, Wyoming, Colorado, New Mexico, and Texas, with summer headquarters at Denver, Colo. His duties comprised the planning and supervision of all topographic mapping in this area.

On December 10th, 1915, he was appointed Acting Chief Geographer of the Topographic Branch of the United States Geological Survey, in which capacity he served until his death.

* Memoir prepared by Frank Sutton, M. Am. Soc. C. E.

Mr. Tatum was one of those rare combinations of thorough ability, good judgment, and consideration of the rights of others, and his death was a great loss, both to his associates in the Survey, with whom he had served for twenty years, and to his wide circle of friends.

C. L. Carpenter, M. Am. Soc. C. E., Manager of the Central Aguirre Company, of Central Aguirre, Porto Rico, writes of Mr. Tatum as follows:

"I believe there was hardly a person on the Isthmus during the time he was there who was so universally respected and liked by the people to whom he reported and by the people who reported to him, and I can hardly think of a person on the Isthmus to whom this would apply so well during the four years that I was connected with the Panama Canal. He certainly was a very loyal employee of the Isthmian Canal Commission and a very loyal friend. He was an extremely good judge of human nature and a good executive, and he did a great deal to help in training many young men while he was on the Isthmus.

"I know very few men who had all Mr. Tatum's good qualities, and it is certainly a pity that he should be called away so soon."

Mr. Tatum was a member of the Washington Society of Engineers and of the Cosmos Club of Washington. He also belonged to a Mississippi Commandery of Knights Templar.

He was married on May 5th, 1909, to Miss Sarah Richardson, of Huntsville, Ala., a daughter of Representative William Richardson and Elizabeth Benagh Rucker Richardson, and is survived by his wife.

Mr. Tatum was elected a Member of the American Society of Civil Engineers on January 4th, 1910.

EDWARD CLINTON TERRY, M. Am. Soc. C. E.*

DIED APRIL 6TH, 1908.

Eli Terry, of Plymouth, Conn., began to make mantel clocks in 1814, and these soon drove other styles out of the market. A few of these mantel or shelf clocks, with wooden wheels and bearing the legend "Warranted if well used", are still sometimes found in Connecticut. His son Eli continued the manufacture of clocks at Terryville, Conn., a village which he founded about 1825, and his grandson James inherited the business, later turning it into the manufacture of locks for trunks. James Terry was of a highly mechanical turn of mind; he installed a pipe organ and a water motor in his house, and also made a working model of a steam road vehicle which walked on four legs like a horse.

Edward Clinton Terry, the youngest child of James and Elizabeth (Hollister) Terry, was born at Terryville on December 10th, 1850. As a lad, he had the advantage of learning much from his father regarding machinery and hydraulic motors. He prepared for college at the High School, in Hartford, Conn., and took the Civil Engineering course at the Sheffield Scientific School of Yale University, from which he was graduated in 1871. As a student, his work was well and faithfully done, and among his classmates he was regarded as a clear thinker, fond of philosophical discussions, and as an excellent chess player.

During 1871-73, Mr. Terry worked as a Rodman on the Easthampton Branch of the Connecticut River Railroad, and was also engaged on surveys of the reservoirs for the water supply of Hartford, Conn. He then spent much time in the study of water meters, and took out patents for both a rotary and a piston meter. The first of these had a wabbling disk which caused the rotation of an axis that acted on the recording apparatus; this he called the "Undine Meter", the name being taken from a German story which was read by his class in the Freshman year. In 1880, he became connected with the Hartford Meter Company, with which he was associated until 1889, at first as General Manager and Secretary, and, later, as its proprietor.

In 1890, Mr. Terry was one of the organizers of the Farmington River Power Company, and, as its Engineer, he designed and constructed a plant for generating electric power on the Farmington River and transmitting it a distance of 11 miles to Hartford. This work included a dam 500 ft. long and 18 ft. high, the hydro-electric power plant, and the transmission line. It delivered at first 800 h.p. to the

* Memoir prepared by Mansfield Merriman, M. Am. Soc. C. E.

Hartford Electric Light Company, and, later, this was increased to 1 300 h.p. This plant is said to have been the first long-distance transmission of power by electricity in America. He was Secretary of the Company and Manager of its engineering work for several years, and it was during this period that modern methods were first used in generating electric energy from water power and in transmitting it to Hartford.

About 1888, Mr. Terry became interested in steam turbines and, in the following ten years, took out patents for three of high speed and three of low speed. In 1906, he organized a company for the manufacture of low-speed turbines, of which he was President until his death. Two of the first turbines were installed in New York City at the Waterside Stations of the Edison Company, and were used to drive boiler-feed pumps; in 1917 there are 24 such steam turbine-driven pumps in use at these Stations. Altogether, about 3 300 Terry turbines have been made and put into operation since 1906.

Mr. Terry had a wide reputation as a man of mechanical genius and high business capacity. Although rather retiring in manner and of a modest disposition, he was cheerful in temperament. Those who became his friends always remained such, admiring his independence of thought, his power of keen analysis of political and philosophical problems, and his sterling character.

In college, Mr. Terry was a member of the Book and Snake Fraternity and of the Sheffield Chess Club. In Connecticut, he was a member of the Hartford Club and of the Golf Club. In politics, he was always an independent voter. In 1901, he went to Europe, but his inclination for travel was never great, and he preferred the quiet of his home and the conversation of his family and friends. He died on April 6th, 1908, at his residence in Hartford, Conn., following a week's illness of pneumonia.

Luther W. Burt, Esq., formerly City Engineer of Hartford, writes as follows:

"Terry always met an acquaintance with a cordial greeting and a pleasant smile. His conversation was always informing and never intrusive. I cannot remember that he ever spoke a disparaging word of any one. He was upright, studious, and self-centered. He had, I think, few intimates, but he generously recognized the services of friends and employees."

Henry W. Sargent, Esq., Vice-President of Sargent and Company, of New Haven, Conn., writes:

"Graduating as a Civil Engineer, Terry's inherited mechanical instincts led his imaginative and reflective mind into mechanical and electrical fields, which he enjoyed and enriched. With this taste and with capacity for practical invention, he possessed executive qualities,

in a nice command of others, with patience to lead his associates to reason and work with him in the direction of his choice. Such power, strengthened by personal morality and a high ethical sense, makes for a leader of men.

"Terry's nervous energy too early wore out a not too strong physique, and he was called to his fathers at a time when his exertions had just placed his manufacturing company on the firm foundation of developing and supplying what was wanted in a field of prime movers all its own."

James Shepard, Esq., of New Britain, Conn., who was Attorney for Mr. Terry in taking out his patents for water meters and steam turbines, writes as follows:

"My acquaintance with 'Clinton Terry' (as he was generally called), began about 1878, when he became my client. He was one of the most interesting clients I ever had, and it was always a pleasure to meet him. He generally had some useful information to impart, oftentimes upon matters other than the main subject of our interviews. He was cheerful, energetic, diligent, persistent, and generally successful in all his undertakings. He was free to express his opinion as to what he wanted, but he always did so in a courteous and pleasant manner. He was a man of good habits, strictly honest, and prompt in all business matters. His inventions were always fully worked out, even as to details, and reduced to working drawings, before making applications for patents. He was liked by all with whom he came into contact, and his influence upon others was of an elevating character.

"His persistency enabled him to overcome obstacles that would have discouraged other men. As an illustration of this, he came into possession of the first clock model made by his great-grandfather, Eli Terry, after a lengthy controversy and the payment of $1 000 for the clock."

Mr. Terry was married on February 28th, 1872, to Miss Louise Ellen Webster, of Terryville, Conn., who survives him. They had two children: Charles Webster Terry, who died in 1886; and James Terry, who was graduated from the Sheffield Scientific School in 1895, succeeded his father as President of the Terry Steam Turbine Company, and died in 1917.

Edward Clinton Terry was elected a Member of the American Society of Civil Engineers on February 6th, 1895.

ERLE LEROY VEUVE, M. Am. Soc. C. E.*

DIED MARCH 25TH, 1917.

Erle Leroy Veuve was born at the Military Post, at Port Townsend, Wash., on January 21st, 1877. His early education was received at Post Schools in many different parts of the country.

In 1893 he went to work as Chainman for the Northern Pacific Railway Company and attained the position of Levelman. In the fall of 1895, he entered Troop Polytechnic Institute, at Pasadena, Cal., with the intention of taking up the profession of Civil Engineering. In 1896 he entered the Civil Engineering Department of Stanford University, where he continued his studies until 1900. During this time, Mr. Veuve's summer vacations were spent in engineering work on the Northern Pacific and Southern Pacific Railways, and for irrigation companies in the San Joaquin Valley, California. During a part of 1898 he served as Chief Yeoman in the United States Navy.

During the latter part of 1900 and the early part of 1901, Mr. Veuve had charge of a number of short pieces of work. In March, 1901, he became Engineer in charge, for the United Verde and Pacific Railway Company in Arizona, superintending the extensive reconstruction on that road. On the completion of this work, in April, 1902, he was employed as Assistant Chief Engineer of the Pacific Electric Railway Company, in Los Angeles, Cal., first in charge of location and, later, of construction. Mr. Veuve handled much of the extensive development work required in the construction of the Company's inter-urban system. In addition to the railroad lines, this work covered a wide field of engineering and construction.

In 1908, further extensions of the Pacific Electric Railway having been discontinued, Mr. Veuve resigned and went into private practice as Consulting Engineer, with offices in Los Angeles. He was engaged in this practice at the time of his death, which occurred very suddenly and unexpectedly on March 25th, 1917, from cardiac asthma. During the last two years of his life, he had been associated with the writer, under the firm name of Veuve and Strong. As a Consulting Engineer, Mr. Veuve's practice covered a wide field, though, in the main, it was connected with the preliminary investigations of electric railway, hydro-electric, and irrigation projects, much of which was of a confidential character. His ability in this field was well known, and his loss will be felt by an exceptionally large circle of friends and business associates.

* Memoir prepared by A. M. Strong, Assoc. M. Am. Soc. C. E.

On October 27th, 1908, Mr. Veuve was married to Miss Anna M. Heim, of Santa Rosa, Cal. He is survived by his widow, his mother, a son, and a daughter.

Mr. Veuve was elected a Junior of the American Society of Civil Engineers on September 3d, 1901, and a Member on February 2d, 1909. He was also an Associate Member of the American Institute of Electrical Engineers, a member of the Engineers and Architects Association of Southern California, and of the Jonathan Club, of Los Angeles, Cal.

THEODORE VOORHEES, M. Am. Soc. C. E.*

DIED MARCH 11TH, 1916.

Theodore Voorhees, eldest son of Benjamin F. Voorhees and Margaret E. Sinclair, was born in New York City on June 4th, 1847. Mr. Voorhees was a direct descendant in the male line from Stephen Coert Van Voorhees, who came to America from Holland, settling at Flatlands, Brooklyn, N. Y., in 1660. His mother was of Scotch parentage, the Sinclairs having come to America in 1835.

He received his education at Anthon's Grammar School, New York City, Columbia University (where he entered the class of 1868, but left in full standing in 1866), and the Rensselaer Polytechnic Institute, at Troy, N. Y., which he entered in 1866 and from which he was graduated in June, 1869. One month later Mr. Voorhees entered the service of the Delaware, Lackawanna and Western Railroad, as Engineer on the extension from Great Bend to Binghamton. So successful was his work and so progressive were his methods, that in less than 2 years he was made Superintendent of the Syracuse, Binghamton and Oswego Division of this railroad. He held this position for 2 years, and then returned to the Engineering Department of the main road, with headquarters at Scranton, Pa.

Although the love of engineering was undoubtedly responsible for this move, Mr. Voorhees' ability as an operating official, which continued throughout his life, had already developed, and this drew him into the Transportation Department of the Delaware and Hudson Canal Company, in December, 1874. Three months later he was made Superintendent of the Saratoga and Champlain Divisions, a position which he held for more than 10 years. He resigned on October 20th, 1885, to become Assistant General Superintendent of the New York Central and Hudson River Railroad. On March 1st, 1890, Mr. Voorhees was made General Superintendent of this road, and, in 1891, was also appointed General Superintendent of the Rome, Watertown and Ogdensburg Railroad Company. While General Superintendent of the New York Central and Hudson River Railroad he saw his road adopt the controlled manual block signal system on its main line from New York City to Buffalo, N. Y. This was one of the most radical advances in railroad signal practice up to that time. At about the same time (1891), the New York Central put on the Empire State Express, with the phenomenal run of 440 miles in 8 hours, or 55 miles an hour. Mr. Voorhees was the operating head of this achievement, which advertised the New York Central all over the world.

* Memoir prepared by Samuel T. Wagner, M. Am. Soc. C. E.

Largely on account of his combined ability as a railroad engineer and operating official, he was made Vice-President of the Philadelphia and Reading Railroad on February 1st, 1893.

He was called to his new duties when but 46 years of age, and at a most critical period of the railroad's history. Emerging from a state of financial depression, after having passed through several receiverships, the road was in a condition of physical disability. So bad were the conditions financially that, in 1896, the property was sold under foreclosure proceedings. Mr. Voorhees was the operating head during these troublesome times, and was one of the foremost factors in the development of the property of the company. This development was entirely intensive, as the following figures will show:

	1893.	1915.
Mileage	1 170	1 120
Revenue ton-mileage	1 739 000 000	3 141 026 000
Passenger mileage	240 488 000	360 468 000
Earnings	$22 986 000	$46 715 000

These figures show a great development in the freight service, but Mr. Voorhees was also instrumental in perfecting the passenger service, and this will always remain as a monument to him. On May 8th, 1914, he was elected President of the road, succeeding the late George F. Baer.

He was also President of the following subsidiary railroads: Philadelphia, Newtown and New York; Philadelphia and Reading Terminal; Philadelphia and Chester Valley; Philadelphia, Harrisburg and Pittsburgh; Tamaqua, Hazelton and Northern; Reading, Marietta and Hanover; Dauphin and Berks; Philadelphia and Frankford; Schuylkill and Lehigh; and the Williams Valley.

He was a Trustee of his Alma Mater, the Rensselaer Polytechnic Institute, a member of the Holland Society of New York, the Century Club of New York, and St. Nicholas Society of New York; the Huntington Valley Country Club, Racquet Club, Philadelphia Club, and Automobile Club of Philadelphia. He was also a member of Psi Upsilon Fraternity.

One of the honors conferred on Mr. Voorhees was his election to the Vice-Presidency of the American Railway Association in 1904. He was also a Director of the Market Street National Bank of Philadelphia.

He was married, on September 19th, 1871, to Sarah V. Gould, daughter of Judge George Gould, of Troy, N. Y. She died on August 7th, 1872, and on February 4th, 1874, in Syracuse, N. Y., he married Miss Mary E. Chittenden, and is survived by a brother and by his widow, five sons, and three daughters.

It has been said of him:

"Theodore Voorhees belonged to a good school of railroad men. He had a conscience and he had ability. Regarded by many as cold and unapproachable, he was, nevertheless, extremely well qualified to solve all those larger transportation problems which in recent years have vexed the public mind. The dead President of the Philadelphia and Reading Railway was one of these, and an important one, who helped raise the Company from a condition of financial weakness into a state of affluence. By doing that he, with his associates, made their railroad of infinitely greater service to the country it serves than it had ever been during its years of financial ill luck. Mr. Voorhees knew railroading through and through, knew what it had to do to meet popular support and what it had to do to maintain its own self-respect and ability to serve. Alert and keen, industrious and honest, intelligent and full of courage, he could not fail in this generation of vast business development to rise to one of the conspicuous railroad positions of the world."

Another said:

"As a man, there is much to be said of Mr. Voorhees. Of austere presence and striking personality, he commands the respect and esteem of all who come in contact with him. He is a man of very few words. He has always time to listen, and treats his subordinates with the utmost courtesy and respect. His friends all testify to his loyalty and kindness. Those who have had an insight into his private life have characterised his devotion as extraordinary."

For a number of years Mr. Voorhees was a Vestryman of St. Luke's Protestant Episcopal Church, Philadelphia, in which he felt a great interest.

His funeral was held at his home in Elkins Park on Tuesday, March 14th, 1916. About 400 prominent railroad officers, bankers, and professional men were present. As a mark of respect, all trains throughout the Reading System were brought to a stop for one minute, at 11 A. M., the hour of the funeral services.

Mr. Voorhees was elected a Member of the American Society of Civil Engineers on May 6th, 1885. He served as a Director in 1890.

EDMUND BROWNELL WESTON, M. Am. Soc. C. E.*

DIED DECEMBER 9TH, 1916.

Edmund Brownell Weston, the son of the Hon. Gershom Bradford and Deborah (Brownell) Weston, was born in Duxbury, Mass., on March 25th, 1850. He was descended from a family famous as shipbuilders and shipowners whose vessels were known in every seaport of the world. In 1842, the firm, the E. Weston Company, was rated by Lloyd's, of London, as the greatest shipping concern in the world. Mr. Weston's father was a member of the Convention which nominated John C. Fremont for the Presidency in 1856, and also of that which nominated Abraham Lincoln in 1860. His mother belonged to the Brownell family of Little Compton, R. I.

Mr. Weston was educated in the public schools and at the Partridge Academy of his native town, the Highland Military Academy at Worcester, Mass., and by private tutors.

From 1871 to 1874, he was a student in the office of the late Joel Herbert Shedd, M. Am. Soc. C. E., then Chief Engineer of the Providence, R. I., Water-Works which were being constructed at that time. In 1874, Mr. Weston was appointed Assistant Engineer on that work, and held that position until 1877 when Mr. Shedd resigned. Early in 1877, when Samuel M. Gray, M. Am. Soc. C. E., was elected Chief Engineer and Superintendent of the Water-Works to succeed Mr. Shedd, Mr. Weston was appointed one of his Assistant Engineers, and, in this capacity, had charge of the Water Department until 1897, when he resigned to engage in private practice as a Consulting Engineer.

Mr. Weston had been in poor health for a year, but had only been confined to his bed about two months when his death occurred, from hardening of the arteries, at the Des Brisay Hospital, at Boston, Mass. He is survived by two brothers and one sister, all residing in Boston, Mass.

At the time of his death, Mr. Weston was President of the Jewell Export Filter Company, of Providence, R. I., and was widely known as a hydraulic engineer. He had designed and constructed filtration systems, in connection with water-works, in many cities, both in America and abroad, and had traveled practically over the civilized world studying systems of water filtration wherever he went. Until the war broke out in Europe, in 1914, he had spent every summer abroad.

In addition to his practical work on hydraulics, Mr. Weston had contributed much to the literature on the subject, his best known

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

work being "Friction of Water in Pipes", published in 1873. He had also contributed many discussions and four papers on the subject to the *Transactions* of the Society, namely, "Description of Some Experiments on the Flow of Water Through 2½-Inch Rubber Hose and Nozzles of Various Forms and Sizes, Made in the Providence, R. I., Water-Works. Also Results of Investigations Relating to the Height of Jets of Water" (1884); "Description of Some Experiments Made in the Providence, R. I., Water-Works, to Ascertain the Force of Water in Pipes" (1885); "The Results of Investigations Relative to Formulas for the Flow of Water in Pipe" (1890); and "Test of a Mechanical Filter" (1900).

Mr. Weston was a member of the University Club, of Providence, R. I.; the India House Club, of New York City; the Boston Society of Civil Engineers; the Institution of Civil Engineers of Great Britain; and the Authors and Royal Societies of London, England. He was also a member of Corinthian Lodge, F. and A. M., of Providence, R. I.

The following resolution on the death of Mr. Weston was adopted unanimously by the Directors of the Jewell Export Filter Company:

Resolved: That the Company and the Board of Directors have suffered a great loss in the death of Mr. Edmund B. Weston, so long the President and General Manager of this Company, and its Consulting Engineer, and that the Board take this occasion to express its appreciation of the long and faithful service that Mr. Weston rendered the Company, fully realizing that he at all times gave the Company that valuable service which was the result of his intimate knowledge of the business and affairs of the Company and the matters in which it has been engaged, and further realizing that Mr. Weston rendered this service oftentimes handicapped with the discouragement of physical ailments which would have taxed the determination of men less faithful than he; and it is further

Resolved: That copies of the above resolution be sent to the Executors of Mr. Weston's estate.

Mr. Weston was elected a Member of the American Society of Civil Engineers, on December 6th, 1882.

EDWARD THOMAS WRIGHT, M. Am. Soc. C. E.*

DIED MARCH 29TH, 1917.

Edward Thomas Wright was born at Elgin, Ill., on June 30th, 1851. His parents were Paul R. Wright and Emily Grace (Harvey) Wright. He attended the public school at Geneva, and, later, at Cobden, Ill., where the family moved when he was about nine years of age. After graduating from the public schools, he had a private tutor for a year and then attended the Elgin Academy.

After leaving the Academy, Mr. Wright took up the study of engineering, and, in 1872, entered the office of Messrs. Cleveland and French, prominent engineers of Chicago, Ill., and was employed by them on work at Indianapolis, St. Paul, and Chicago, including the South Chicago Drainage, for the development of an industrial district.

Mr. Wright moved to Los Angeles, Cal., in the latter part of 1874 and established himself as a Civil Engineer and Surveyor, maintaining his office up to the time of his death, on March 29th, 1917. He had served three terms as County Surveyor, and was a hydraulic engineer of ability, having done much effective work in developing underground waters and constructing irrigation systems.

In 1873 Mr Wright was married to Lucy Nicholson, who died in 1899. He leaves two sons, George A. and Charles N., who follow his profession, and a widow, Mrs. Capitola B. (Wenzel) Wright, whom he married in March, 1912.

He was a man highly respected for his sterling worth and honesty; ever ready to help others, and loved by many friends.

Mr. Wright was elected a Member of the American Society of Civil Engineers on February 3d, 1886.

* Memoir prepared by W. D. Larrabee, M. Am. Soc. C. E.

AUGUSTUS WATEROUS AGNEW, Assoc. M. Am. Soc. C. E.*

DIED SEPTEMBER 17TH, 1916.

Augustus Waterous Agnew, the only son of William Agnew, now of Victoria, B. C., was born at Montreal, Que., Canada, on June 6th, 1884. He received his engineering education at the Royal Military College, Kingston, Ont., Canada, and at the Crystal Palace Practical School of Engineering, London, England.

Returning to Canada, Mr. Agnew began his professional career, in January, 1906, on preliminary and location surveys for the Canadian Pacific Railway, with headquarters at Montreal, Que.

In July, 1906, he went to Saskatchewan as Instrumentman on the construction of the Grand Trunk Pacific Railway. In December of the same year, he went to Prince Rupert, B. C., where he was employed, as Resident Engineer, on hydrographic, topographical, and town-site surveys, and also on sewer construction, under James H. Bacon, M. Am. Soc. C. E., then Harbor Engineer, Grand Trunk Pacific Railway.

In May, 1909, Mr. Agnew left the employ of the Grand Trunk Pacific Railway to engage in private practice as a member of the firm of Ritchie, Agnew, and Company, with offices at Prince Rupert, B. C. Among other work, this firm had charge of the construction of the first water supply system for the City of Prince Rupert, including three dams, and 14 miles of supply and distribution mains. The firm was also engaged on wharf design and construction; the supervision of surveys, plans, stream measurements, and estimates for a permanent municipal water supply and power project; investigation surveys, etc., for power projects for the Prince Rupert Hydro-Electric Company, Limited, as well as the design and supervision of the subdivision of a town site of 1 000 acres, including topographical and hydrographic surveys and harbor layout, adjoining Prince Rupert, with R. H. Thomson, M. Am. Soc. C. E., acting as Consulting Engineer, and numerous small sewerage and water supply schemes, and water-power investigations.

In 1913, Mr. Agnew became interested in the development of a large water-power at Stamps Falls, near Alberni, Vancouver Island, capable of developing 75 000 h. p., and prepared extensive plans, the development of which, owing to the outbreak of the war, had to be postponed. Mr. Agnew's valuable work on this project will no doubt later bear fruit.

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

In the spring of 1914, he moved to Victoria, B. C., where he took the contract for laying the sewer system of Esquimalt which he completed.

When the 48th Battalion, Canadians, was mobilized there for service in the European war, he transferred from the Corps of Guides to that Battalion, and went overseas as its Captain and Adjutant. The Battalion, through the efforts of Captain Agnew and a few of its officers, went to the front as a unit and an Engineering Battalion of the 3d Canadian Division, and was afterward known as the 3d Canadian Pioneer Battalion. Then it was that Captain Agnew's engineering training came into service, and he made a reputation for it that became known among many of the other Canadian and British Battalions. In April, 1916, after six weeks in Belgium, constructing trenches in the Ypres salient, Captain Agnew was seriously wounded in the head and right arm by high explosive shrapnel, and subsequently suffered the loss of his left eye. After a month in the hospital, he went to Hythe, in Kent, England, where, during his sick leave, he voluntarily gave much needed instruction to non-commissioned officers and men of the Pioneers Depot at South Cæsar's Camp, Shorncliffe, England. He was offered a position as Major on the 3d Canadian Divisional Staff, but as he was eager to get back with his men, he obtained shortened leave and, on August 1st, took command once more of his old Company at the front. After six weeks he was again dangerously wounded while preparing the trenches for the infantry to hold during the battle of Courcelette, on September 15th, and died after an operation, at a Casualty Clearing Hospital near Amiens, France, on September 17th, 1916.

Captain Agnew will be greatly missed by all who knew him well enough to appreciate his many fine personal qualities as well as his ability as an engineer. He was well liked by his fellow officers and by the men whom he had trained and with whom he had fought. The splendid state of organization and efficiency reached by his Battalion was due largely to his tireless energy and ability in engineering and leadership.

He was an Associate Member of the Canadian Society of Civil Engineers, and an Associate Member of the Society of Engineers (Incorporated), of London, England.

Captain Agnew was elected an Associate Member of the American Society of Civil Engineers on July 2d, 1913.

WILLIAM FREDERICK ALFRED ANSON, Assoc. M. Am. Soc. C. E.*

DIED JULY 17TH, 1916.

William Frederick Alfred Anson, the son of the Rev. Alfred W. Anson, was born at Staunton, Va., on August 7th, 1878. He received his early education under governesses and tutors in his home and in England. In 1893, he entered the Episcopal High School, at Alexandria, Va., where he remained until 1896. He then entered Roanoke College, at Salem, Va., where he remained for one year, after which he entered the Virginia Military Institute, at Lexington, Va. He attended the Institute for three years, but was unable to complete his course on account of ill-health. After leaving school, he remained on his father's farm until 1902.

In July, 1902 Mr. Anson entered the employ of the Norfolk and Western Railway Company, as Instrumentman and Inspector on construction work. He remained with this Company until 1907. He then went to Martinsville, Va., where he was engaged in private surveying until 1908.

He was then appointed Inspector in Campbell County under the Virginia State Highway Commission, and, later, was promoted to Resident Engineer by the Commission, with headquarters at Pulaski, Va., having charge of the work in several counties. In April, 1914, he was again promoted by the Commission to be County Engineer of Russell County, with headquarters at Lebanon, Va.

For several years before his death Mr. Anson had been in poor health, and in January, 1916, he went to Richmond where he was examined by a specialist who pronounced his trouble to be chronic appendicitis. He returned to his home in Lebanon, but soon decided to undergo an operation, and, in February, 1916, was operated on at the Bluefield Sanatorium, Bluefield, W. Va. He never fully recovered from this operation, although he returned to his work which he carried on until about a week before his death.

In his professional career Mr. Anson developed those qualities which insure success. He had been connected with the highway work in Russell County only a short time, but he was highly thought of by all the citizens, and the County road authorities were more than satisfied with his management.

In October, 1915, Mr. Anson was married to Miss Vera Seay, of Eagle Rock, Va. He is survived by his widow, his father, brother, and nine sisters.

Mr. Anson was regarded as an engineer of rare ability, and his work with the Virginia State Highway Commission has always been

* Memoir prepared by A. H. Pettigrew, Esq.

highly commended. He was a man of high principles and of strong convictions, never hesitating to stand up for what he thought to be right or to oppose that which he considered wrong. He was a devoted member of the Protestant Episcopal Church, which he had joined in his youth, and he will be greatly missed by his family and his friends and associates.

Mr. Anson was elected an Associate Member of the American Society of Civil Engineers on October 1st, 1912.

ROBERT HAMMOND BOYNTON, Assoc. M. Am. Soc. C. E.*

DIED SEPTEMBER 18TH, 1916.

Robert Hammond Boynton, the son of the late Henry P. and Emma (Hammond) Boynton, was born at Batavia, N. Y., on May 21st, 1886. He received his early education in the public schools of his home town, having been graduated from the High School in 1903. In September, 1904, he entered the Civil Engineering Department of the University of Michigan, where he remained until June, 1906, when he left college to enter the employ of the New York Central and Hudson River Railroad Company, as Chainman on grade reduction between Syracuse and Rochester, N. Y. In April, 1907, he was advanced to the position of Rodman on the same work, but resigned in October, 1907, to return to the University of Michigan, from which he was graduated in June, 1910, with the degree of Bachelor of Science in Civil Engineering.

On July 1st, 1910, Mr. Boynton entered the employ of the Missouri Pacific Railroad Company, as Rodman in the Maintenance of Way Department, with headquarters at St. Louis, Mo., being in charge of track renewal and engaged in general office and field work connected with the Department. In June, 1911, he was transferred to the Construction Department, with headquarters at Marianna, Ark., as Inspector of bridge construction on the Marianna Cut-off. In March, 1912, he was again transferred to the Illinois Division, with headquarters at Illmo, Mo., as Assistant Engineer engaged in routine office and field work connected with the Maintenance Department.

In December, 1912, Mr. Boynton entered the service of the Mississippi River Commission as Recorder on a river survey between Fort Jackson and Port Eads, La.

On April 1st, 1913, he was appointed City Engineer of Frankfort, Ind., by the Mayor, Dr. O. W. Edwards, to fill an unexpired term. In January, 1914, Mr. Boynton was re-appointed to the same office by the newly elected Mayor, Dr. Oliver Gard, and remained in that position until his death, on September 18th, 1916, following a long illness resulting from heart trouble and a complication of diseases, due to exposure and malaria contracted while he was engaged on engineering work in the Southwestern States.

Mr. Boynton was considered one of the best City Engineers that Frankfort, Ind., ever had. He had charge of the design and construction of all street and sewer improvements, and through his efforts a complete set of street and sewer records of the city was made, thereby giving the Municipal Government its first check on sewers, streets,

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

and property owners. He had also completed a map of the City of Frankfort, which has been widely used by those interested in its public improvements.

Mr. Boynton had a genial disposition and readily made and held as friends all who met him. He was most efficient and honest, and through his conscientious efforts and steady application to duty, he received and maintained for his Department perfect work from the contractors employed thereby. He was an expert on filing systems, and at the time of his death was preparing himself for the work of a Consulting Engineer and City Manager.

Mayor Oliver Gard writes of him, as follows:

"Our city was deeply shocked when, on September 18th, the death of Robert H. Boynton, City Engineer, was announced. While he had not been a resident of this city for many years, yet we had learned to regard him highly. His work as City Engineer had been very laborious, but always satisfactory. His efficiency was never questioned. We regret his untimely death."

Mr. Boynton was married on October 15th, 1912, to Miss Zua Rice, a daughter of Mr. and Mrs. John A. Rice, of Frankfort, Ind., who, with his mother, Mrs. Emma Boynton, and a brother, R. Rae Boynton, of Rochester, N. Y., survives him.

He was a member of the Presbyterian Church of Frankfort, Ind., and of Masonic Lodge No. 475, of Batavia, N. Y. He was also a member of the American Society of Municipal Improvements, the Municipal League of Indiana, the Akhenaton Society of Ann Arbor, Mich., the Alumni Association of the University of Michigan, and the Chamber of Commerce of Frankfort, Ind.

Mr. Boynton was elected a Junior of the American Society of Civil Engineers on May 6th, 1914, and an Associate Member on April 18th, 1916.

FRANS ENGSTRÖM, Assoc. M. Am. Soc. C. E.*

DIED MARCH 20TH, 1916.

Frans Engström, the son of Ludwig and Frederika Engström, was born in Stockholm, Sweden, on November 28th, 1851. He was educated in his native city and was graduated from the Latin College and the Royal Polytechnical High School.

After his graduation, Mr. Engström was engaged, for two years, in an architect's office on private surveys, and also as Assistant Resident Engineer on the construction of the Government Railway of Sweden.

In 1881, he came to the United States and settled in Pittsburgh, Pa., where he was engaged with the Pennsylvania Railroad Company, as Draftsman, Chief Draftsman, and Assistant Engineer, until 1895. During this time, he designed and superintended the construction of the Penn Street Freight Station in Pittsburgh, and made plans and specifications for extensive dock construction at Erie, Pa., and at Ashtabula and Cleveland, Ohio. He also made the plans and specifications for all heavy bridge masonry and retaining walls on the Company's lines and for elevating its tracks through Pittsburgh and Allegheny.

In 1895, Mr. Engström was appointed Assistant to the Director of Public Works of the City of Pittsburgh, which position he resigned in 1899. While serving in this capacity, he built the large twin reservoirs at Highland Park, for the Pittsburgh water supply.

During 1899 and 1900, he was engaged in private practice as Civil and Hydraulic Engineer, with an office in Pittsburgh. In 1901, Mr. Engström was appointed Civil Engineer with the Carnegie Steel Company, retaining that position until 1903, when he entered the service of James Stewart and Company as Engineer of Inspection.

In 1905, Mr. Engström went to the American Bridge Company, at Ambridge, Pa., where he remained, as Engineer, until March, 1907. In April, 1907, he removed to Altoona, Pa., where he had been appointed City Engineer, retaining that office until 1915. As City Engineer Mr. Engström had charge of extensive paving work, supervised the planning of the East Altoona disposal plant, built the Seventh Street Bridge, and had charge of other important municipal improvements.

In 1915, Mr. Engström returned to Pittsburgh, but his health having failed, he was not able to engage actively in his profession. He had only been discharged from the hospital where he had been

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

undergoing treatment for five months, when his sudden death from heart failure occurred on March 20th, 1916.

Mr. Engström was a talented and highly educated man. He spoke seven languages, and, being a great reader, was well informed, not only regarding his Profession, but on all subjects of general interest. Among his professional friends, he was considered one of the best estimating engineers in Pennsylvania.

On August 25th, 1884, Mr. Engström was married to Miss Bertha Lindstrum, who, with four children, survives him.

He was a member of the Engineers' Society of Western Pennsylvania, Duquesne Commandery No. 72, Knights Templar, and Syria Temple of Shriners, of Pittsburgh, and of Altoona Lodge No. 102, Benevolent Protective Order of Elks.

Mr. Engström was elected an Associate Member of the American Society of Civil Engineers on May 4th, 1892.

HOWARD ARNOLD GREENE, Assoc. M. Am. Soc. C. E.*

DIED FEBRUARY 2D, 1917.

Howard Arnold Greene was born at Providence, R. I., on September 15th, 1860.

Immediately after his graduation from Brown University, in June, 1884, Mr. Greene entered the employ of S. B. Cushing and Company, Engineers and Surveyors, and remained with that firm until April, 1887. While with this Company, Mr. Greene was engaged on the construction of the Diamond Hill Reservoir for the Pawtucket, R. I., Water-Works, on the greater part of the line of the Union Street Railroad Company, and, as Assistant Engineer, on all the preliminary work for the Providence Cable Railroad Company and the improvements of the Park Land Company, at Elmwood, R. I.

In April, 1887, Mr. Greene was appointed Division Engineer with the Hudson Connecting Railroad Company, under the late P. P. Dickinson, M. Am. Soc. C. E., as Chief Engineer, on the Poughkeepsie Bridge route. When this was finished, in September, 1888, he accepted a position as Engineer for J. W. Coffin and Company, Contractors for the Brigantine Beach Railroad, which position he retained until August, 1889, when he went to the Dunderbergh Spiral Railroad Company, as Division Engineer, until work on that line was stopped.

In December, 1889, Mr. Greene was appointed Locating Engineer with the Danville and East Tennessee Railroad Company. He remained in that position until May, 1890, when he entered the employ of Morris and Darly, Engineers and Contractors, of Bristol, Tenn., as Assistant Engineer on surveys for the State of Virginia and on the erection of a blast furnace at Bristol, Tenn.

In December, 1890, Mr. Greene was engaged as Engineer in charge of the construction of the terminal pier at Atlantic Highlands, N. J., for the Central Railroad of New Jersey. He afterward went to Connecticut as Assistant Engineer on the location of about 30 miles of railroad, under the late Joseph Norton Greene, M. Am. Soc. C. E., as Chief Engineer.

In November, 1892, Mr. Greene entered the employ of the New Jersey Steel and Iron Company as Assistant Engineer. He was promoted, until at the time of the incorporation of the American Bridge Company, he was in charge of erection in the New York District.

In July, 1901, he was appointed Erection Manager of the Pittsburgh Division for the American Bridge Company, which position he

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

held at the time of his death. While serving in this capacity, Mr. Greene had charge of the erection of many important structures and had invented a number of important erection devices which are patented.

He died of pneumonia at his home in Pittsburgh, Pa., on February 2d, 1917, after a brief illness, and is survived by his widow.

Mr. Greene was elected an Associate Member of the American Society of Civil Engineers, on June 5th, 1895.

WILLIAM HERBERT HYDE, Assoc. M. Am. Soc. C. E.*

DIED APRIL 15TH, 1917.

William Herbert Hyde, the son of Peter Lowe and Anne Elizabeth (Copcutt) Hyde, and the grandson of the late John Copcutt, of Yonkers, N. Y., was born at the latter place on December 15th, 1874. He was of English descent, one great-grandfather having been an officer (Captain) in the Revolution and another in the War of 1812. Both his grandfather and his father were engaged in the mahogany and hardwood export and import business in New York City.

Mr. Hyde received his education at the public and grammar schools, and the Yonkers High School, and, in 1895, entered the employ of the New York Central and Hudson River Railroad as Chainman in the Chief Engineer's Department, advancing to Assistant Engineer of the Maintenance of Way Department in 1898. From that time until 1901 he served on location and construction with the Erie Transit Company and the Panama Railroad; on topographical work and estimates for the Barge Canal, New York State; and as Assistant Engineer in the Atlantic City, N. J., Water Department.

During 1901 Mr. Hyde was engaged in surveying and contracting work, being associated with Pittsburgh interests. In April, 1902, he entered the contracting field, forming a partnership with his father-in-law, Mr. W. F. Patterson, of Pittsburgh, Pa., and specialized in shaft and underground improvement work.

During the last ten years, he had conducted his business alone, his operations including coal shafts in Pennsylvania, West Virginia, Nova Scotia, and Alberta, Canada. He built many fine concrete-lined pumping stations underground and successfully completed contracts for such firms as the New River Company, The Berwind-White Company, The Ragland Coal Company, and others of equal standing. He often contributed articles of merit to leading engineering and mining journals, and has been freely quoted as an authority in works on coal mine engineering.

Mr. Hyde died at Scarboro, W. Va., on Sunday, April 15th, 1917, from a bullet wound received while attempting to place an unruly workman under arrest.

He was married on February 15th, 1903, to Miss C. Virginia, daughter of Walter F. Patterson, of Pittsburgh, Pa., who, with four young children, survives him.

Mr. Hyde was a member of the Sons of the Revolution. He was elected a Junior of the American Society of Civil Engineers on April 30th, 1901, and an Associate Member on June 4th, 1902.

* Memoir prepared by S. M. Van Loan, M. Am. Soc. C. E.

JOSÉ PETRONIO KATIGBAK, Assoc. M. Am. Soc. C. E.*

DIED MAY 16TH, 1916.

José Petronio Katigbak was born at Lipa, Batangas, Philippine Islands, on October 4th, 1879. His parents, Mariano Katigbak and Isabel (Macarandang) Katigbak, both of Lipa, Batangas, were wealthy hacienderos, and belonged to the most prominent families in the Province.

His preliminary education was obtained in the Ateneo Municipal de Manila, a school conducted by the Jesuit Order, from which he was graduated, with the degree of B. A., in 1896, at the head of his class.

He then studied medicine for one year in the University of Sto. Tomas, Manila, but this not being to his liking, he decided to study engineering, and while preparing himself to go abroad, he taught Spanish literature in the High School of his native town during 1898 and 1899, his services being given free for the benefit of his countrymen.

Mr. Katigbak then went to Europe and traveled extensively through France, Italy, Germany, and England, and, in 1900, entered King's College of the University of London, from which he was graduated in June, 1903, with the degree of Qualified Civil Engineer and the Certificate of Distinction.

He then entered the Lawrence Scientific School of Harvard University and was graduated with the degree of S. B. in Engineering, in June, 1904.

Subsequent to his graduation, he took the 1904 Special Summer Course at Harvard, specializing in Plane, Railroad, and Geodetic Surveying. On finishing this course, Mr. Katigbak entered the employ of S. D. Warren and Company, of Westbrook, Mass., remaining with that company for 7 months in the capacity of Draftsman, Surveyor and Designer.

In 1905, he returned to his native land and obtained a position with the Bureau of Public Works, where he was employed for about 4 months as Transitman, laying out the City of Baguio in accordance with the plans prepared by G. E. Burnham, Assoc. M. Am. Soc. C. E.

On February 5th, 1906, Mr. Katigbak was transferred to the Department of Engineering and Public Works of the City of Manila, and remained in the service of the City until his death. His promotion was rapid, as may be seen from his service record: February 5th, 1906, Surveyor (temporary); July 1st, 1906, Transitman (probationary); April 1st, 1907, Assistant Engineer; May 1st, 1908, Chief Surveyor; June 1st, 1910, Second Assistant City Engineer; June 3d, 1910, Instruc-

* Memoir prepared by A. Gideon, M. Am. Soc. C. E.

tor in Graphics, University of the Philippines, in addition to his other duties; October 1st, 1911, Superintendent of Streets and Bridges; March 4th, 1914, First Assistant City Engineer.

On several occasions, during the absence of the City Engineer, Mr. Katigbak was Acting City Engineer, and, as such, Acting Member of the Municipal Board. He was a faithful, conscientious, and hard worker, although he was not very robust. The continuous strain of his official duties undermined his health, and, in May, 1916, he left Manila on a short vacation to his home town to recuperate. While there, he contracted typhoid fever. He came back to Manila and had the benefit of the best medical talent, but his health was so undermined that he succumbed to the disease, and died on the morning of May 16th, 1916.

Mr. Katigbak's talents were varied, and he took a great interest in the fine arts, such as painting, poetry, etc. His paintings, while still a student in the Ateneo de Manila, now decorate the walls in several Government offices.

He was of a very happy disposition, and had many friends both in and out of official life, and his death was mourned by the whole population of the Philippine Islands. On the day of his funeral, all flags in Manila were half-masted, and all the City offices were closed. More than 20 000 people were in the funeral cortège. Among the honorary pall-bearers, were the Mayor and the Municipal Board, the chiefs of all the City offices, Justices of the Supreme Court, and many prominent men in civil life. The route of the procession for some miles was decorated with palms and thronged with sympathizers.

The following bodies, organizations, and offices marched in the funeral procession: Department of Engineering and Public Works; the Municipal Board of Manila; Local Members of the American Society of Civil Engineers; The Society of Engineers and Architects of the Philippines; The Columbian Association; the Bureau of Public Works, and many other organizations.

The Municipal Board, by resolution, set aside a plot for the deceased in the area reserved for the burial of illustrious and heroic dead, and, in addition, adopted the following resolution of condolence:

"EXCERPT FROM THE MINUTES OF THE MUNICIPAL BOARD OF MAY 16, 1916.

"*Whereas,* the Almighty in His Infinite wisdom has seen fit to remove from our midst our most esteemed friend and former public official, Mr. José P. Katigbak, who departed this life Tuesday, May 16th, 1916; and

"*Whereas,* it is the desire of this Body to express its condolence to the family, friends, and relatives of the deceased and its appreciation to the public generally of the efficient manner in which his services to the City of Manila as a public official had always been performed; now, therefore, be it

"*Resolved:* That the sincere sympathy and condolence of the Municipal Board be, and the same hereby are, extended to the immediate family, relatives, and friends of the late José P. Katigbak and that an expression of commiseration be tendered to them in this, their hour of bereavement; and be it further

"*Resolved:* That this Body do, and it hereby does, publicly express its keen appreciation for the manifold labors performed by him as a City official; for the betterment of conditions in the City of Manila; and be it further

"*Resolved:* That the flag at the City Hall building be displayed at half-mast until the funeral day, inclusive, on which date the flags on all City buildings shall be similarly displayed; and be it further

"*Resolved:* That a certified copy of these resolutions be sent to the widow and father of the deceased and to His Excellency, the Governor-General; and be it further

"*Resolved:* That this Board attend in a body the funeral ceremonies to be held over the remains of our departed friend."

At a later session of the Board, it was decided to name one of the principal streets, facing the New Luneta, Katigbak Boulevard.

Mr. Katigbak was married, in 1910, to Miss Trinidad Buenaventura, who, together with his father, two brothers, and one sister, survives him. He was very fond of children and his greatest regret was that he had no issue.

Mr. Katigbak was a member of The Institute of Engineers and Architects of the Philippine Islands, of which he was the first President. He was also a member and one of the founders of the Philippine Columbian Association, a society made up of Filipinos who have received college degrees in the United States.

Mr. Katigbak was elected an Associate Member of the American Society of Civil Engineers on April 1st, 1914.

GEORGE GERE MacCRACKEN, Assoc. M. Am. Soc. C. E.*

DIED AUGUST 1ST, 1913.

George Gere MacCracken, the son of Henry Mitchell MacCracken (Chancellor Emeritus of New York University), and Catherine (Hubbard) MacCracken, and a grandson of the Rev. John Steele MacCracken, of Ohio, and the Rev. Thomas Swan Hubbard, of Vermont, was born on March 8th, 1878, at Toledo, Ohio.

He was educated at the Lyons Collegiate Institute, Broadway and 21st Street, New York City, and, in 1894, entered the New York University School of Applied Science, from which he was graduated in 1898 with the degree of B. S., receiving the degree of C. E., in 1899. He was Inman Fellow at New York University during the college year of 1898-99, and also took special courses in electricity at the Columbia University School of Mines. In 1899, he was awarded the Hoe Sanitary Engineering Prize for the best work in sanitary investigation.

In 1899, Mr. MacCracken was appointed to the Engineering Staff of the Manhattan Railway Company. He remained with that Company until 1902, when he became Assistant Engineer of the Interborough Rapid Transit Company, holding that position until 1908. His principal work with these companies was the supervision of the construction of the Elevated Railway Terminal Yards at 159th Street and the Harlem River and at Third Avenue and 179th Street. These yards cost about $500 000 and required very skillful engineering.

In 1908, he organized the Alboro Contracting Company, of which he became President, and, later, the MacCracken, Hauer, Terry Company, engaging in the general contracting business.

Mr. MacCracken was of large and commanding presence and was possessed of a genial nature, although rather exclusive in his choice of associates. His thorough preparation for engineering work, coupled with his industrious and conscientious nature, gave promise of substantial accomplishment.

He lost his life by drowning off Glen Cove, Long Island, on August 1st, 1913, having been stricken by heart failure after the exertion of bringing his launch through a severe storm on Long Island Sound. He was buried in Sleepy Hollow Cemetery, at Tarrytown, N. Y.

Mr. MacCracken was married on April 29th, 1907, to Martha J. Hall, the daughter of the late John H. Hall, who, with one son, Williston Ward MacCracken, born in 1910, survives him.

* Memoir prepared by George H. Pegram, President, Am. Soc. C. E., and Charles H. Snow, M. Am. Soc. C. E.

During his college course, Mr. MacCracken was a member of the Psi Upsilon Fraternity, the Red Dragon Senior Society, and the Chemical Society, and was President of the Engineering Society. Later, he was a Trustee of the American Savings Bank of New York, and a member of the Railroad Club and the Psi Upsilon Club.

Mr. MacCracken was elected a Junior of the American Society of Civil Engineers on February 5th, 1901, and an Associate Member on February 3d, 1904.

STANLEY HASTINGS McMULLEN, Assoc. M. Am. Soc. C. E.*

DIED JULY 12TH, 1916.

Stanley Hastings McMullen, the third son of the late H. D. McMullen, was born at Aurora, Ind., on June 4th, 1872. He received his early education in the public schools of his home town, leaving the High School to enter the United States Naval Academy at Annapolis, Md., in May, 1893. He was obliged, on account of ill health, to leave the Naval Academy during his third year, and in September, 1895, he entered Purdue University where he took the course in Civil Engineering.

In May, 1899, Mr. McMullen entered the employ of the Illinois Central Railroad Company, as Track Apprentice. He remained with this Company until September, 1903, having attained the position of Resident Engineer in charge of construction. He was obliged to go West on account of his health and from September, 1904, to January, 1905, was engaged with the State Engineer of Colorado on the Colorado-Kansas Irrigation suit then before the Courts. On his return East he served as Division Engineer on 14 miles of construction for the Indianapolis and Louisville Traction Line, from April to December, 1906.

In January, 1907, Mr. McMullen went to El Paso, Tex., where he was engaged in private surveying until March of that year, when he was appointed City Engineer of Aurora, Ind. He held that position until October, 1907, during which time he planned the sewer system for that city and many street improvements.

Mr. McMullen then returned to Colorado and served as Assistant Engineer with the Denver Reservoir and Irrigation Company until January, 1908, when he returned to Anderson, Ind., to engage in the private practice of engineering.

In September, 1913, he accepted a position as Assistant City Engineer and Draftsman at El Paso, Tex., which he held until April, 1915. Mr. McMullen afterward devoted his time to private practice in and around El Paso, and also at Lake City, Fla., until May, 1916, when he returned to Jeffersonville, Ind., fully intending within a short time to return to Orlando, Fla., where he had accepted a position. His health had been failing for some time and at the urgent request of his family he entered Christ Hospital, at Cincinnati, Ohio, where he died after an operation undertaken in a last effort to save his life.

In 1901 he was married to Miss Laura Frank, of Jeffersonville, Ind., who, with his three brothers, survives him.

* Memoir prepared by the Secretary from information on file at the Society Headquarters.

Mr. McMullen was regarded as an engineer of exceptional ability and his work was always highly commended by his superiors. Owing to the fact that he was obliged, on account of his health, to live and work in many different parts of the country, his experience covered almost every phase of engineering work. He was a man of indomitable will power and of strong convictions, never hesitating to stand up for that which he deemed to be right or to oppose that which he considered wrong. He was a loyal and devoted member of the Methodist Episcopal Church which he had joined in his youth, and he will be greatly missed by his family, his friends, and associates.

Mr. McMullen was a member of the Indiana Engineering Society, and was elected an Associate Member of the American Society of Civil Engineers on November 3d, 1915.

PHILIP HENRY PARTHESIUS, Assoc. M. Am. Soc. C. E.*

DIED FEBRUARY 15TH, 1916.

Philip Henry Parthesius, the eldest son of Dorathea Jordan and Julius Parthesius, was born at Troy, N. Y., on December 15th, 1881. He received his early education in the public schools of Troy and, later, attended the Rensselaer Polytechnic Institute, from which he was graduated with high honors in 1904, receiving the degree of Civil Engineer.

Mr. Parthesius began his professional work in the Bridge and Construction Department of the Pennsylvania Steel Company, at Steelton, Pa., remaining there about a year. On leaving this work, he became Assistant Engineer on the construction of a large extension to the water-works system of Troy, N. Y. In this capacity, he was engaged in the building of storage reservoirs, pipe lines, dams, controlling works, etc. On the completion of this work which took about 3 years, Mr. Parthesius became connected with the New York State Civil Service Commission at Albany, in the capacity of Engineering Examiner, and, in October, 1913, he was made Assistant Chief Examiner of this Commission.

While with the Civil Service Commission, he had much to do with the preparation and rating of examinations for engineering positions in all State Departments, including those of the State Engineer and Surveyor, Public Service Commission, and the Highway Department, all of which required a large number of men to handle the extensive work on the Barge Canal, New York City subways, and the improved highway systems.

Mr. Parthesius was a wide reader and a keen student; a man of calm, even temperament, a true friend and gentleman, who possessed the confidence and respect of those who had the pleasure of his acquaintance. His early demise removed from the Profession one who was deeply devoted to his work, and who was just entering the pathway leading to a successful career in engineering work. His sudden illness and death was deeply lamented by a wide circle of friends and associates. He died on February 15th, 1916, after a brief illness.

Mr. Parthesius was unmarried, and is survived by his mother and one brother, Henry J. Parthesius, also a civil engineer.

He was a member of the Albany Society of Civil Engineers and of the Eastern Society of Civil Engineers.

Mr. Parthesius was elected an Associate Member of the American Society of Civil Engineers on November 1st, 1910.

* Memoir prepared by H. O. Schermerhorn, Assoc. M. Am. Soc. C. E., Troy, N. Y.

LEWIS ROBERTS POMEROY, Assoc. Am. Soc. C. E.*

DIED MAY 7TH, 1917.

Lewis Roberts Pomeroy was born at Port Byron, N. Y., on February 5th, 1857, but his early life was spent in Milwaukee, Wis., where his father was in business. In his fifteenth year he came East, and attended school at the Irving Institute in Tarrytown, N. Y., for one year. His subsequent education was obtained entirely by his own efforts, for, from this time, he supported himself by filling various clerical positions until, in 1880, he became Secretary and Treasurer of the Suburban Rapid Transit Company, which position he filled until 1886.

From 1886 to 1895 Mr. Pomeroy was with the Carnegie Steel Company, during which time he introduced basic boiler steel for locomotives and special forgings. He was a painstaking student of locomotives and locomotive details, and exerted a strong and effective influence in improving such materials and in the detailed design of locomotives. Subsequently, he was engaged in the same kind of work jointly for the Cambria Steel Company and the Latrobe Steel Company. From 1899 to 1902, he was Assistant General Manager of the Schenectady Locomotive Works, and from 1902 to 1908, he was representative in the railway field for the General Electric Company.

Engineers owe Mr. Pomeroy a debt of gratitude for his studies in the electrification of steam railroads, for his knowledge and experience enabled him to reveal many important phases of this problem. His earlier work in connection with electric power in railroad and manufacturing shops was of great importance in methods of modernization, and he was undoubtedly among the highest authorities on railroad shop layouts and equipment.

Mr. Pomeroy's next appointment was as Assistant to the President of the Safety Car Heating and Lighting Company, and, subsequently, he was appointed Chief Engineer of the Railway and Industrial Divisions of J. G. White and Company. In June, 1914, he was appointed Manager of the New York Sales Office of the United States Light and Heating Company, but later opened an office as Consulting Engineer in New York City.

Mr. Pomeroy had been in the railway and railway supply business for more than thirty-five years, and many officials and engineers, especially those connected with railroads and railroad developments, will sadly miss his friendly helpfulness. His own wide engineering knowledge came through painstaking study, experience, and contact.

* Memoir prepared by George M. Basford, Esq., New York City.

His kindly nature was attracted to young men who were struggling to succeed; his natural desire was to encourage and aid them, and to lead them to improve and to take important places in the world's work. Would that we had more men inspired as he was with the desire to help others! It became an important part of Mr. Pomeroy's life-work to discover young engineers of ability and to bring them to the front, and this will be to him an enduring monument.

His death, which was very sudden, occurred at his home in East Orange, N. J., on May 7th, 1917. He is survived by his wife and two children.

Mr. Pomeroy was elected an Associate of the American Society of Civil Engineers on April 2d, 1890.

WILLIAM THOMAS SHAW, Assoc. M. Am. Soc. C. E.*

DIED FEBRUARY 26TH, 1916.

William Thomas Shaw, a son of Ebenezer A. and Betsey S. (Dunham) Shaw, was born in Middleborough, Mass., on May 6th, 1880. His father was a veteran of the Civil War.

From the local schools, Mr. Shaw went to Dartmouth College where, as at home, he was a renowned exponent of the National game, filling the positions of pitcher and first baseman on the 'Varsity nine. He was a member of the Phi Delta Theta fraternity, and of the Senior Society, Casque and Gauntlet.

After receiving the degree of B. S., in 1904, he entered the Thayer School of Civil Engineering, an associated school at Hanover, N. H., founded in 1871 by Gen. Sylvanus Thayer, father of the United States Military Academy. There he was well grounded in the fundamentals of Civil Engineering, under the directorship of that able and scholarly professor, Robert Fletcher, M. Am. Soc. C. E. Mr. Shaw rounded out his education by spending the summer and fall of 1904 in surveying; the spring of 1905 as Aide on the Forestry Survey of Dartmouth College Grant, Coos County, New Hampshire; and from June to November, 1905, as Instrumentman on electric railway construction at Sterling, Mass.

Receiving the degree of C. E., in 1906, Mr. Shaw was, for a short time, in the field office of the Charles River Basin Commission, as Computer. In November, 1906, he went to Pennsylvania, where he was employed by the Cumberland Valley Railroad for two months as Assistant to Crosby Tappan, Construction Engineer. He was then put in charge of 6 miles of revision work to eliminate grade crossings, reduce grades, and double-track.

On May 5th, 1909, Mr. Shaw entered the service of the Boston Elevated Railway Company, under the late George A. Kimball, M. Am. Soc. C. E., Chief Engineer. He was employed in the Cambridge Office of the Bureau of Elevated and Subway Construction, first as Computer and Checker, and, later, as Assistant Engineer during the construction of the Main Street Subway. In the latter position, Mr. Shaw was engaged on the design and plans of the Eliot Square Car-House, Cambridge, including foundations, floor, retaining walls, and track layout. The Car-House is the Cambridge Terminal of the Cambridge Subway, and consists of a large area of storage tracks, both covered and in the open, repair shops, etc., for the large cars used in the Subway.

* Memoir prepared by F. S. Weston, Assoc. M. Am. Soc. C. E.

Mr. Shaw was rapidly advancing in his chosen field when, on July 18th, 1911, just as he was about to sign the plans which he had been preparing, he was forced to resign on account of pulmonary tuberculosis. After seeking to regain his health in various places, he returned to Middleborough, Mass., and built a home adjacent to the place of his birth, where he continued to make a brave, but losing, fight against the ravages of the disease, by working in the open air.

He was a clean young man, ambitious, conscientious, with a strong sense of duty and loyalty; of excellent judgment and clear and orderly way of thinking. He had that happy faculty of making friends wherever he went and also retaining them. To the last, he was hopeful and cheerful, laying his plans for the future and ever ready to help others.

On June 30th, 1910, Mr. Shaw was married to Madeleine R., daughter of William Scott and Mary (Bryant) Fleming, of Greencastle, Pa., who survives him.

He was a member of the Boston Society of Civil Engineers and the Thayer Society of Engineers. He was also a member of the First Congregational Church, the Masons, and the Sons of Veterans.

Mr. Shaw was elected an Associate Member of the American Society of Civil Engineers on June 30th, 1910.

WILLIAM STUART SMITH, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 5TH, 1916.

William Stuart Smith was born in Troy, N. Y., on April 15th, 1856. He was the eldest of three children, and was descended on both sides from Revolutionary ancestors. His grandfather, Captain Levi Smith, was a contemporary of Commodore Vanderbilt in the steamboat business, and his father, William Stuart Smith, was long connected with the New York Central Railroad. His mother was Delia Marble Newton, of Bennington, Vt.

He was educated at private schools and the College of Montreal, and after removing with his parents to Rochester, N. Y., in his seventeenth year, he attended the school of Professor George Hale.

Mr. Smith's first engineering work was with a field party during the four-tracking of the New York Central Railroad. On June 1st, 1876, he entered the office of the City Surveyor, of Rochester, and, in 1883, he was made First Assistant.

In 1886, he entered the employ of the Warren-Scharf Asphalt Paving Company, which, in 1900, became The Warren Brothers Company, of Boston, Mass. Mr. Smith was also District Manager of The Warren Chemical Company, of New York City, and carried on a large roofing business. In 1914, he purchased the Western New York rights of The Warren Chemical Company, and conducted the business under the name of The W. Stuart Smith Company. He continued his connection with The Warren Brothers Company, and, at the time of his death, was a Director and Vice-President of that Company. Mr. Smith was frequently consulted and generally recognized as an expert in paving and roofing.

About fifteen years ago he was interested in a plantation operated by The Indian River Pineapple Company.

Mr. Smith was a man of fine address and had a lovable personality. He had hosts of friends whom he entertained at his summer home, Sunny Side, at Pultneyville, N. Y., on Lake Ontario. He was a lover of fine horses, and maintained a dashing span long after the automobile had come into vogue.

He was a member of many professional, social, patriotic, and athletic organizations, a Thirty-second Degree Mason, and a communicant of Christ (Episcopal) Church, of Rochester, N. Y.

On September 4th, 1879, he was married to Minnie Pomeroy Sackett, of Rochester, who survives him. He is also survived by two

*Memoir prepared by John F. Skinner, M. Am. Soc. C. E.

brothers, Charles S. Smith, of Connecticut, and Frederic Levi Smith, of Rochester, two sons, Captain Lawrence N. and Donald Stuart Smith, two daughters, Mrs. Marion Elizabeth Stafford, and Mrs. Carol Content Gard, and four grandchildren.

Mr. Smith was elected an Associate Member of the American Society of Civil Engineers on January 8th, 1902.

SAMUEL FORSYTHE THOMSON, Assoc. M. Am. Soc. C. E.*

DIED JANUARY 30TH, 1917.

Samuel Forsythe Thomson was born in Charleston, S. C., on June 5th, 1872. His parents were Samuel and Elizabeth Craig Forsythe Thomson, natives of County Antrim, near Belfast, Ireland, who came to Charleston at an early age, were married and made their home there. His father was a prominent merchant in Charleston for many years, and was well and favorably known throughout that section of the South, being prominently identified with many of the activities of his community.

Mr. Thomson first attended a public school in Charleston, and, after finishing the course there, entered the Charleston High School, from which he was graduated with honor in June, 1889. A life-long friend of the family testifies to the fact that he was a favorite alike with teachers and pupils. He then attended a school at Boylston and Tremont Streets, Boston, Mass., where he was prepared for a higher education. Mr. Thomson entered the Massachusetts Institute of Technology in September, 1890, and specialized in civil engineering.

During the summer vacations of 1891 and 1892 he was engaged on engineering work with the firms of Aspinwall and Lincoln and E. A. W. Hammatt, Civil Engineers, of Boston, Mass., and during the summer of 1893 attended the summer school of the Institute of Technology at Keeseville, N. Y. In the summer of 1894 he was employed with John W. Arnold, United States Marshal, of Chicago, Ill., and later for a short period was with the late Col. George E. Waring, Jr., in the Department of Street Cleaning, New York City.

During 1895-96 Mr. Thomson took an additional course at the Institute of Technology in railroad engineering. He was graduated from the Institute in June, 1896, with the degree of Bachelor of Science in Civil Engineering.

After graduation he re-entered the service of the Department of Street Cleaning of New York City under the Commissioner, Col. George E. Waring, Jr., and until May, 1898, was a member of his personal staff. During his administration as Commissioner, Col. Waring gained an international reputation by reorganizing the Department, introducing many reforms, and placing it on an efficient and business-like basis. Mr. Thomson acted as Chief Assistant to the Master Mechanic, and had charge under his supervision of the design and erection of two steel storage dumps, also the general design and repairs to city property, such as stables, dumps, and scows, and of snow removal above 59th Street, Manhattan. He also supervised the introduction of the system of separation of city refuse throughout

* Memoir prepared by Robert Ridgway and George A. Taber, Members, Am. Soc. C. E.

the entire city, and of the construction and operation of the first crematory used for the economical utilization of city wastes for the development of power.

From May, 1898, to April, 1903, Mr. Thomson was the Assistant to the Professor of Civil and Military Engineering at the United States Military Academy, West Point, N. Y., and then entered the service of the Commission on Additional Water Supply for the City of New York, this commission having been appointed to investigate all available sources for an additional water supply for the city. Mr. Thomson was in charge of the New York office of the Long Island Department, under Walter E. Spear, M. Am. Soc. C. E., which Department was engaged in the investigation of the available underground supply on Long Island.

On July 23d, 1903, he was appointed an Assistant Engineer in the Engineering Department of the Rapid Transit Railroad Commission, of New York City, and was assigned to the Fifth Division under Robert Ridgway, M. Am. Soc. C. E., Division Engineer, on the construction of the rapid transit tunnels under the East River from South Ferry, Manhattan, to Joralemon Street, Brooklyn, which tunnels are now in operation. He had much to do with the triangulation and other survey work in connection with the alignment of the tunnels, and for a time was in charge of the general office management of the Division. He resigned on March 5th, 1906, to accept an appointment as Assistant Engineer in the service of the Board of Water Supply of the City of New York, of which J. Waldo Smith, M. Am. Soc. C. E., was Chief Engineer, and was assigned to the Wallkill Division of the Northern Aqueduct Department by the Department Engineer, Robert Ridgway. The Wallkill Division, with headquarters at New Paltz, included about 12 miles of Catskill Aqueduct construction, which aqueduct was designed for a daily capacity of 500 000 000 gal. The most notable feature of construction was the deep rock pressure tunnel, 4.4 miles long, under the Wallkill Valley, this tunnel being located at a maximum depth of about 520 ft. below the hydraulic gradient. Other features of construction were the south half of the Bonticou grade tunnel through the Shawangunk Mountains, about 6¾ miles of cut-and-cover aqueduct on the slope of these mountains and on the east side of the Wallkill Valley, and the blow-off chamber and conduit leading from the aqueduct to the Wallkill River. The cost of construction of the work on the Division was approximately $5 500 000. For a time Mr. Thomson was in charge of the organization of the division office, and was instrumental in establishing methods and a routine which proved to be most efficient in carrying out the work. Following the transfer to other work of James F. Sanborn, Assoc. M. Am. Soc. C. E., Division Engineer, Mr. Thomson, on February 1st, 1912, was made Acting Division Engineer in his place, and so remained until the practical completion of the work.

Of his record on the Wallkill Division, Ralph N. Wheeler, Assoc. M. Am. Soc. C. E., now in charge of the Northern Aqueduct Department, writes:

"His work as an organizer of a working force and of systems of routine, records, filing, etc., was unusual. In no other division of this department were records kept so faithfully and well, supplies, equipment, etc., so completely accounted for, and large and small matters relating to the work so completely recorded. I shall always believe that this was due very largely to Mr. Thomson's faithful oversight. His loyalty to his superiors, consideration for his subordinates and in fact his every-day devotion to his work, even in the small and often disagreeable details, are the characteristics for which we shall always remember him."

On June 15th, 1914, he left the service of the Board of Water Supply and accepted employment with the Kingsbridge Contracting Company, of New York City, as Civil Engineer. He was identified with the operations of that company, particularly in the construction of the large outlet sewer which was built in connection with the Seventh Avenue Rapid Transit Subway, from that avenue to the Hudson River, the cost of this sewer being about $500 000. He was also connected with the construction of the large trunk sewer in East 41st Street, as well as with other projects carried out by that company.

On his return home from the excursion during the Annual Meeting of the American Society of Civil Engineers, on January 18th, 1917, Mr. Thomson was stricken with the illness which resulted in his death twelve days later.

A friend, of many years standing, who knew the personal as well as the business side of his character, writes:

"To those who knew him intimately many of his finer qualities were alone revealed. His friendship possessed those priceless and rare characteristics which endeared him to all who were privileged to be counted among his friends. Its endurance was unquestionable, and at all times his active and unqualified support to a friend could always be depended upon. His sense of honesty was also of the highest quality. In all his dealings the moral obligation in a business transaction was as important and binding to him as any of the legal provisions, and this quality characterized all of his acts through life. He was in all respects an ideal friend, in the finer sense of the word, and none could desire or have a better."

Another associate of his in his later work says:

"I consider him one of the finest characters I have ever met. In the three years of our acquaintance and friendship we were together considerably during business hours and out of them. At all times and under all conditions, many of which were often trying, his pleasant smile and cheery way never left him. He was very careful not to hurt any one's feelings, and never spoke disparagingly or unkindly of any

person; he generally had some explanation or excuse for the failings of the one who might be under discussion and who had not measured up to the full stature of a man."

Loyalty to his principles and to his friends, honesty, humanity, and steadfastness of purpose were prominent among the underlying qualities of his nature, and the character built on such a foundation was one which his friends will long remember with affection and pride.

Mr. Thomson was married on September 29th, 1898, to Miss Jennie A. Milton of Danvers, Mass., who with one daughter, Elizabeth, survives him. He was a member of the New England Water Works Association, the Municipal Engineers of the City of New York, and the Brooklyn Engineers Club. He was much interested in the work of the Fourth Unitarian Church, of Brooklyn, N. Y., of which he was a member.

Mr. Thomson was elected an Associate Member of the American Society of Civil Engineers on January 3d, 1906.

GEORGE EDWARD VANSITTART, Assoc. M. Am. Soc. C. E.*

DIED MAY 14TH, 1916.

Major George Edward Vansittart, 13th Battery, 4th Canadian Field Artillery Brigade, died on May 14th, 1916, from shell wounds received while on active service somewhere in France.

The only son of John Pennyfather Vansittart, Public Works Department, India, George Edward Vansittart was born at Mussooree, India, on October 7th, 1884. He came of a long line of naval and military ancestors, on both sides. His great-grandfather and his uncle on his father's side were Admirals in the British Navy, and Bisham Abbey, in Berkshire, was for many years the home of his great-grandfather, of which branch of the family he was the last young male representative. His great-grandfather on his mother's side was Colonel Alexander Light who commanded with distinction in India, and elsewhere, the 25th Queen's Own Borderers.

George Edward Vansittart came to Canada at an early age, and was a graduate of the Royal Military College of Canada and also of McGill University. At the conclusion of his University career, in 1906, he adopted the profession of Civil Engineering. During the next two years he was employed as Resident Engineer on the construction of the Midland Railway of Manitoba and Assistant Engineer on the Canadian Pacific Railway Irrigation Project, at Calgary, Alberta.

In the spring of 1909, Mr. Vansittart was engaged by Messrs. Smith, Kerry and Chace, Consulting Engineers, of Toronto, Ont., as Assistant Engineer on the construction work of the Crane Falls Power and Irrigation Company, of Boise, Idaho. Before severing his connection with this Company to enlist for active service, he held the position of Vice-President and General Manager.

When the Great War broke out, this gallant officer returned to Canada and enlisted as a subaltern in the Field Artillery, where his great ability gained for him rapid promotion, and, in a short time, he was gazetted as Major and given command of a battery. By the time his battery reached England, it was considered to be the smartest and most efficient unit in the artillery of the division to which it belonged. Decorations and further rapid promotions were prophesied for Major Vansittart, whose untiring energy, able judgment, and sound gunnery had impressed every one who came into contact with his work. A Canadian Staff Officer writing a personal letter said:

* Memoir prepared by F. H. Peters, Assoc. M. Am. Soc.

"Vansittart is the best battery commander of the outfit, and his gun positions are the pride of the district. Neighboring artillerymen are sent down to see them as a model of what gun positions should be. The enemy have never located them."

Major Vansittart was mentioned in a despatch from General Sir Douglas Haig, published June 15th, 1916, for gallant and distinguished service in the field.

George Edward Vansittart was elected an Associate Member of the American Society of Civil Engineers, on March 5th, 1912. He was also an Associate Member of the Canadian Society of Civil Engineers.

JAMES MADISON WARNER, Assoc. M. Am. Soc. C. E.*

DIED MARCH 5TH, 1916.

James Madison Warner, a son of the late William H. Warner, was born at Syracuse, N. Y., on August 4th, 1882. He was educated in the public schools of that city, and was graduated from the High School. In 1902, he entered the University of Illinois from which he was graduated in June, 1908, with the degree of B. S. in Civil Engineering.

Prior to entering college and during his summer vacations, Mr. Warner had been employed by the Chicago and Western Indiana Railroad Company as Chainman, Rodman, and Instrumentman on the work of track elevation into Chicago, Ill.

In 1908, he accepted a position as Instrumentman with the Grand Trunk Pacific Railroad Company, in connection with the grading and alignment of about 30 miles of track from Winnipeg, Man., west, and in 1909, he was engaged in the same capacity on track revision and grade alignment for the Chicago and Northwestern Railroad Company, at La Crosse, Wis.

Later in the same year, Mr. Warner went to Oralo, Tex., as Resident Engineer on 17 miles of construction on the Pecos and Northern Texas Railroad, a branch of the Santa Fé System. On the completion of this work in 1910, he was transferred to Sweetwater, Tex., where he had charge of the construction of 13 miles of heavy construction, large yards, a 600-ft. dam, etc.

In 1912, he abandoned railroad engineering and returned to Syracuse, N. Y., as Chief Engineer of the Onondaga Litholite Company, of which his brother, Mr. Henry P. Warner, is President. In addition to his duties as Chief Engineer, Mr. Warner became prominently identified with the general management of the business until March, 1915, when he was stricken with appendicitis. An operation followed, but complications developed which caused his death on March 5th, 1916, at the Syracuse Hospital for Women and Children.

While at college Mr. Warner had been prominent in student affairs, and was regarded as one of the most popular members of the undergraduate body. In his professional and business career, he had developed those qualities which insure success, and, despite his comparative youth, he had already won for himself a leading place in the industrial activities of Syracuse. His manly qualities of mind and heart had won for him many friends, and his death was a severe loss to them and to his family. Mr. Warner is survived by two brothers,

* Memoir prepared by the Secretary, from information on file at the Society Headquarters.

Mr. Henry P. Warner, of Syracuse, N. Y., and Mr. Robert K. Warner, of Ouray, Colo., and by two sisters, Mrs. Henry K. Chadwick and Mrs. George A. Hanford, of Syracuse, N. Y.

He was a member of the Delta Tau Delta Fraternity, University of Illinois Chapter, the Citizens, Onondaga Golf and Country, and the University Clubs, of Syracuse, N. Y., and Champaign Lodge, B. P. O. E.

Mr. Warner was elected a Junior of the American Society of Civil Engineers on April 6th, 1909, and an Associate Member on December 3d, 1913.

WILLIAM COOPER CUNTZ, Assoc. Am. Soc. C. E.*

DIED NOVEMBER 2D, 1916.

William Cooper Cuntz, the son of the late Emil A. H. Cuntz and Frances Cooper Cuntz, was born at Hoboken, N. J., on January 21st, 1871. His maternal grandfather, William Cooper, after whom he was named, was a well-known naturalist and one of the founders of the New York Academy of Science. His maternal grandmother, Mary Wilson, was of New England ancestry, going back to the days of the Pilgrims, and including officers and soldiers in the Revolutionary Army.

Mr. Cuntz was educated at the Hoboken Academy and at Stevens Institute of Technology, having been graduated from the latter in 1892 with the degree of Mechanical Engineer. He then became connected with the Pennsylvania Steel Company, of Steelton, Pa., first with the Bridge and Construction Department, which he represented as Resident Engineer in Boston, Mass., and as European Resident Engineer, in London, England. In these capacities he rendered many important services to his Company, notably in connection with the erection of the North and South Stations in Boston, and in securing the contract for the construction of the North German Lloyd piers, in Hoboken, N. J. He afterward entered the Sales Department, serving as Assistant General Manager of Sales, in Philadelphia, Pa., and, later, as District Sales Manager, in Steelton, Pa.

At the outbreak of the Spanish-American War in 1898, Mr. Cuntz volunteered for service in the Artillery. In 1910, he was appointed by President Taft as a delegate to the International Railway Congress held at Berne, Switzerland, the present Secretary of the Interior, the Hon. Franklin K. Lane, being the Chairman of the American Delegation.

In the same year (1910), Mr. Cuntz severed his connection with the Pennsylvania Steel Company to become a Director and the General Manager of the Goldschmidt Thermit Company, of New York City, which position he held until his death which occurred on November 2d, 1916, at Auburndale, Mass., where he had gone on a visit for the benefit of his health which had been impaired by an operation for appendicitis a year before. Under his management the business of this Company was not only increased greatly, but equal progress was made in the technical development of the Thermit process. His wide experience in the steel industry naturally caused him to take a particular interest in the manufacture of carbon-free metals, and it is due

* Memoir prepared by W. R. Hulbert, Esq.

largely to his perseverance and initiative that these metals and alloys are coming into such general use.

He is survived by his widow, who was Miss Katherine Hughes Edwards, of Hagerstown, Md., a descendant of Jonathan Edwards, and by his two children, William Cooper, Jr., and Emil Edwards. He is also survived by two brothers, John H. Cuntz, of Hoboken, N. J., and Hermann F. Cuntz, of New York City.

Mr. Cuntz was a member of the following clubs and societies: American Iron and Steel Institute, Engineers Society of Pennsylvania, Engineers Club of New York, Railroad Club of New York, Engineers Club of Boston, University Club of Philadelphia, Chemists Club of New York, Boston Athletic Association, India House, Transportation Club, Harrisburg Club, American Electric Railway Association, New England Iron League, West Side Tennis Club, Richmond Hill Association, Kew Gardens Civic Association, Kew Gardens Country Club, Oak Island Yacht Club, and the Conococheague Club of Hagerstown, Md.

Mr. Cuntz was elected an Associate of the American Society of Civil Engineers, on September 6th, 1910.

GEORGE HENRY FROST, Assoc. Am. Soc. C. E.*

DIED MARCH 15TH, 1917.

George Henry Frost, the son of Ebenezer and Caroline (Harwood) Frost, was born on July 9th, 1838, at West Hawkesbury, Ont., Canada, where his father was engaged in the foundry business. His parents were of New England ancestry, natives of Vermont, who had emigrated to Lawrence County, New York, and, about 1836, had removed to Canada. When Mr. Frost was about a year old, his parents removed to Smith's Falls, Ont., where the boy obtained his early education at the village school. In 1854, he was sent to an academy in Glover, Vt., and on his return to Smith's Falls, he taught school while preparing for college. He was graduated from McGill University in 1860 with the degree of Civil Engineer, and, at the time of his death, was its oldest living alumnus.

After his graduation from McGill, Mr. Frost, as was the custom in those days, served his apprenticeship to a licensed land surveyor, until 1863, when he received his diploma as a Provincial Land Surveyor. His ambitions were not satisfied, however, by the opportunities offered him at his home in Smith's Falls, and, in August, 1863, he went to Chicago, Ill., where he secured employment as Rodman on a railroad survey then being made by the Chicago and Northwestern Railroad in Wisconsin. He remained with that Company, first in the office of the Chief Engineer and afterward in the Land Commissioner's office, until 1868, except for the summer of 1864 when he was employed in an architect's office in St. Louis, Mo.

After leaving the employ of the Chicago and Northwestern Railroad Company, in 1868, Mr. Frost engaged in the private practice of engineering with an office in Chicago. After the great fire in October, 1871, he did a great deal of engineering work in connection with the rebuilding of the city and in the establishment of property lines within the burned district. Many of the suburban sections which have been incorporated as part of the City of Chicago were laid out by Mr. Frost at that time. His work included also the survey of the tracts which now comprise the United States Reservation at Fort Sheridan and the Town of Glencoe.

In April, 1874, Mr. Frost established and issued the first number of the *Engineer and Surveyor*, a monthly publication devoted to the interests of the civil engineer, and the first periodical of its kind in America. In 1876, the publication was changed to a weekly and re-named the *Engineering News*. In December, 1878, Mr. Frost moved his business to New York City and opened an office in the Tribune Building. Later, he transferred his office to the St. Paul Building. The *Engineering News* steadily prospered under his management

* Memoir compiled by the Secretary, from information on file at the Society Headquarters.

until it became known as one of the leading authorities on civil engineering and allied subjects. In 1911, Mr. Frost sold his establishment to the Hill Publishing Company, of New York City, which recently was merged with the McGraw Publishing Company.

Mr. Frost always took great pride in the fact that he had carried the entire first few editions of his paper to the post-office himself, and that, during his 37 years of ownership, the paper had never missed an issue and was always out on time.

In 1886, Mr. Frost became a resident of Plainfield, N. J., and from the first took great interest in the local affairs of that place. When the City authorities were considering a sewerage system for the town, he took an active part in the work, serving, as a member of the Common Council, on the Committee on Streets and Sewers for five years. As Chairman of that Committee in 1893, he drafted the design for the sewerage system and devoted much thought, time, and labor to the project until its completion, in 1896.

After severing his connection with *Engineering News* in 1911, Mr. Frost retired from active business and devoted his time to study and travel. He was deeply interested in the study of genealogy and in geography and history, and he supplemented his reading by travel in many parts of the world. He had visited most of the countries of Europe and had made extensive trips to Egypt, South America, and in the United States. In 1914, he was planning a trip around the world, but gave it up on the outbreak of the European War.

Up to December 23d, 1916, Mr. Frost had enjoyed unusually good health. On that date, he suffered a stroke of paralysis and, although his condition improved for a time, he grew worse again, his death occurring at his home in Plainfield on March 15th, 1917.

On December 3d, 1868, he was married to Miss Louisa Hunt, a daughter of the late Edwin Hunt, of Chicago, Ill., and she, with four sons, survives him.

Mr. Frost was a thorough business man, with a capacity for the smallest as well as the largest detail. He was an optimist by nature, always looking on the bright side of things, his enthusiasm never lagging until his object was accomplished. Being deeply religious, he always took a keen interest in local church and charitable affairs, and was an active member of the Crescent Avenue Presbyterian Church of Plainfield.

Mr. Frost became a citizen of the United States in 1863, and was always afterward associated with the Republican Party. He was a member of the Canadian Society of Civil Engineers, and was also connected with a number of other scientific and technical organizations. At the time of his death, he was President of the Courier-News Publishing Company, of Plainfield, N. J., having purchased that paper in June, 1904.

Mr. Frost was elected an Associate of the American Society of Civil Engineers on January 4th, 1882.

JAMES JEROME HILL, F. Am. Soc. C. E.*

DIED MAY 29TH, 1916.

The death of James Jerome Hill, at St. Paul, Minn., on May 29th, 1916, removed from the railway, banking, and industrial life of the United States one of the most forceful and beneficent figures of his generation. Through the reflex action of his marvelous mind, as demonstrated in the many activities directly affecting the progress and welfare of the world, he became an international character, and will live in the future, in the influence and example of the sound policies and great works that his genius created during the busy years of his life.

In the vast circle of his friends, and among his business associates who knew him as he was, the demonstration of grief at his death was sincere and heartfelt, and the knowledge that such a personal and public loss was inevitable, in the course of Nature, made the sorrow no less poignant.

To condense even the main features of his history and life work within the limits of this memoir would be an impossibility, but, as a Fellow of the American Society of Civil Engineers, it is fitting that some record of his career and activities, and of the encouragement and co-ordination that he gave to the civil engineers who carried out his great works, should be made in the annals of the Society.

Mr. Hill was born near Guelph, Ontario, in the Dominion of Canada, on September 16th, 1838. His parents, James Hill and Anne (Dunbar) Hill, were of Scotch and Irish extraction, his father following the usual occupations of a farmer in a new country. His school education was obtained at Rockwood Academy, an institution of his home neighborhood, conducted by a Quaker schoolmaster, who exercised a strong influence on him and directed his reading and studies. His father died when he was fifteen years old, and he then took his share in the maintenance of the family by working in a country store near-by. His ambition, however, could not long be satisfied with such a narrow field, and three years later, in the summer of 1856, after visiting several of the larger cities of the United States, he settled in St. Paul, Minn.

As a young man without friends or resources, he found employment as a clerk on the river front, then the center of the business life of the little frontier settlement. He was first with the Dubuque and St. Paul Packet Company, then with the Davidson line of steamboats, remaining with that concern until he was appointed Agent of the

* Memoir prepared by Ralph Budd, W. L. Darling, and John F. Stevens, Members, Am. Soc. C. E.

Northwestern Packet Company in 1865. In 1867 he established a general fuel and transportation business on his own account, and in 1869 he became the head of the firm of Hill, Griggs and Company, engaged in the same enterprises. During all these years, by constant study of historical facts, human nature, and conditions, he laid the foundation of a business experience which came to include a knowledge of all the essential facts of the trade of the city and the country back of it, and began to estimate properly the wonderful resources of the latter, the possibilities of which had not even dawned upon our most far-sighted men.

The fuel business, even at that time, was important, and was closely allied with the restricted transportation facilities of the Northwest; but, during this period, Mr. Hill had become interested in the trade between the United States and Fort Garry, as Winnipeg was then called, and which was carried by way of St. Paul. To handle this business, he established, in 1870, the Red River Transportation Company, and in 1872 he started the first regular line of service between St. Paul and Fort Garry. The knowledge he thus gained of the vast latent resources of that country crystalized into one of the dominant ideas of his existence, and one which, extended and amplified beyond his wildest dreams, became an accomplished fact long before the close of his life. So that, as the result of his prophetic vision and tireless energy, an immense section of our country, which had been considered—if at all—of little value, has become a very potential factor in the production of the wealth of the world, and the homes of thousands of the best citizens of which the United States can justly boast. It was on one of his many trips, made in connection with this transportation business, that he met Donald A. Smith, afterward Lord Strathcona, with whom he was to be so closely and successfully associated in his first railroad enterprise.

There came to a troubled life in the Fifties, under the stimulus of legislation in Minnesota, a railway company called the St. Paul and Pacific, which name alone signified ambition, without knowledge or resources. It controlled valuable terminal lands in St. Paul, and had partly built a line, ultimately intended to reach the Canadian boundary at St. Vincent; but the road had failed, and had gone into the hands of a Receiver in 1873. Its bonds were held in Holland, by parties who were not willing to abandon their investment, nor had the foresight or nerve to invest more to salvage the wreck. Mr. Hill alone saw the possibilities of the road, and what a factor it could be made toward the development of the country, an empire then unsettled and overlooked. It was a ready forged but crude instrument, which, to be adequate for his purpose, must be controlled, properly financed, and made effective, all of which appeared to be a hopelessly visionary project, excepting to his master mind.

Its total debt was nearly $33 000 000, an enormous sum for those times, and the very size of this debt would have staggered a less optimistic and forceful character. He believed that he could secure, and bent all his energies toward securing, control of the property, and his faith was justified. The co-operation of Donald A. Smith, and of George Stephen (afterward Lord Mountstephen) was gained, and, together with Norman W. Kittson, who had had experience of the country in acting for the Hudson Bay Company, they formed a syndicate to buy the defaulted bonds of the companies covered by the St. Paul and Pacific Railroad Company.

The detailed story of the next few years reads more like a fairy tale than a relation of the sober facts of history. These four men pledged every thing they had in the world to obtain even money enough to secure an option on the bonds; for men of affairs in New York and London regarded the whole proposition as chimerical. Besides the securing of an option on the bonds, money had to be provided to finish uncompleted lines, within the time limit set by the Legislature, in order to avoid forfeiture; and all of this labor fell upon Mr. Hill, as did also the financing necessary to make good the agreements with the bondholders, until such time as the railroad could become a producer of net revenue, and it was not until 1878 that it could be truthfully said that matters really began to take proper shape.

In 1879 the properties were reorganized as the St. Paul, Minneapolis and Manitoba Railway Company, with necessary lines in operation, an organization created, the proper spirit infused into the enterprise, and a matured plan for the future mapped out. The system then comprised 555 miles of constructed road, and 102 miles under construction. From this time began its steady, never-ceasing expansion, covering the Northwestern country with new lines and branches, to be followed closely by immigration and settlement, and making an equally steady progress towards Montana, and the ultimate goal of the Pacific Ocean, which object had been in Mr. Hill's mind from an early day.

In 1888 the road reached Butte, and in 1893, the Pacific Extension touched the shores of Puget Sound at Seattle, Everett, and Bellingham, realizing the transcontinental idea. A line had long before been completed to the Great Lakes, and a steamship company established to give an eastern outlet.

Mr. Hill was for two years during this period interested in the planning and construction of the main line of the Canadian Pacific Railway, from the plains of Manitoba west to the Pacific Ocean, being Managing Director of that company; but in 1883 he gave up direct connection with that enterprise to devote his entire time to the welfare of his own marvelously developing properties.

He opened trade with the Orient, establishing a line of transpacific ships to develop and handle this new traffic. Locally, wherever his

lines touched, new industries sprang up; immigration and settlement, fostered by him as a personal matter, followed the rails with a rapidity hitherto unprecedented in the history of the United States.

In 1890 the various railroad enterprises which were offshoots of the original plan were all compacted into one company, the present Great Northern System. The great machine was pushed to completion, and grew bigger and better from year to year, until it stands to-day, in character and plan, as a marvel of transportation efficiency.

Mr. Hill was General Manager of the company from its beginning, became Vice-President in 1881, and President in 1882, which office he held and administered until he resigned it to one of his sons, just 25 years later. During all these years, as well as to the end of his life, his was the guiding hand, and his the inspiring vision and controlling mind that have made the Great Northern Railway not only the most notable long-distance transportation machine in the world, but also the greatest single factor in the material development of an empire of incalculable wealth of resources. This system, as the embodiment of the plans, ideas, and acts of one man, alone constitutes a fitting monument to the clear vision and untiring genius of James J. Hill.

As a student of railway economics, Mr. Hill had early known that the measure of success for a road was to be found in its ability to move traffic at the lowest practicable cost. In freight movement, this meant light gradients, with heavy power and large-capacity cars, with consequent maximum train loading. In this field he was preeminently the pioneer in American railroad practice. In the planning and construction of his lines, the cardinal principle, which he insisted must be followed, was that a dollar saved in construction is saved but once, but that a dollar saved in operation, is saved every time the wheels go over the track, and he saw to it that his engineers carried this principle out in every particular. Either by personal inspection or from reliable reports, he knew practically the resources and conditions of every mile of territory into which he projected his lines. He was naturally a great engineer, and always appreciated and gave credit where credit was due, to the different engineers whom he trusted to plan and execute the details of his projects. He quickly recognized merit and ability in the personnel of his engineering staff, and neither seniority nor rank influenced him in the least in preferment or promotions. He was equally quick to criticize and condemn, whenever his usually unerring judgment so dictated, and his attention to details together with his dynamic force of character kept every one of his staff up to the highest point of individual efficiency. But every engineer, however humble his rank, knew that, like Napoleon's soldiers, he carried a baton in his baggage, and the success and preferment of many engineers, not only of the Great Northern, but of other systems, were due, not only to Mr. Hill's forceful example, but also to his direct personal interest in their

welfare. Whenever he gave his confidence and support, he gave freely and fully. Results were what he demanded, and nothing pleased him more than to have an engineer leave the beaten track and find a new and better way to reach such results, and in this way individual initiative was encouraged. The Engineering Profession owes a large debt of gratitude to Mr. Hill, as some who were intimately associated with him for many years know full well, and appreciate.

As evidence of the great respect he had for the Profession, let his own words speak for themselves. In an address delivered before a gathering of Civil Engineers, at Minneapolis, Minn., on January 10th, 1908, he said:

"Yours is a great profession, following as it does the oldest of all the arts. When the pyramids were built there were engineers who mastered problems calling for great engineering skill. Relics of still older civilizations appear from time to time on the sites of cities whose names forgotten tell that the engineer was there also; and that he was, then as now, a leader of thought in matters of great practical service to the common good. The name of your occupation is significant, related as it is to the word 'genius' and implying the union of human ability with that diviner spark which kindles knowledge to a brighter flame.

"The engineer is, indeed, in no mean sense a creator. Not only does he provide for the needs of mankind those practical utilities on which civilization is based, but he brings into being structures, combinations, possibilities of dead matter and natural energy in relations new to men. He is inventor as well as artisan. Many of the modern wonders of the world are the thoughts of his brain as well as the works of his hands. The subjection of Niagara to our daily wants, the redemption of an ancient country by the damming of the Nile, great bridges such as span the Firth of Forth and our own East River at New York, tunnels that carry traffic under the estuary of the Severn and the peaks of the Simplon pass, tubes that enable railways to avoid waters too wide to be bridged safely, canals that cut away land barriers, the modern steamship that has cheapened and quickened ocean transit, the factories that have revolutionized industry and the marvelous plants which are now using the waterfalls of Norway to enrich the earth by the manufacture of fertilizers drawn from the nitrogen of the air—all these are conquests of the engineer's ability and bear tribute to him as the author of heretofore unthought of things. Across every chapter of the story of human development is written the symbol of some great engineer's creative mind."

The financial record of Mr. Hill's labors sufficiently attests to the sagacity of his ideas and their practical execution. While to superficial comment, it may be said that his individual pecuniary reward was great, the fact remains that he was never a money seeker for personal benefit. His whole ambition was to be a faithful custodian of the interests committed to his care, and no charge that he ever failed to make his work good can justly be made against him. His ability to

interest capital—domestic and foreign—in any project, or in line with any plan he set forth, was well known. He proved his faith and words by his acts, and such a course made him almost unique in the history of railroad finance in the United States.

As a characteristic act, his handling of the Great Northern iron ore interests may be mentioned. In 1899 he purchased an insignificant logging road, in northern Minnesota, which owned some lands. These lands contained iron ore, but in unknown quantities. At that time the vast deposits of such ore in that section had not been demonstrated, and his purchase involved a business risk in which he did not care to engage his stockholders. So the property was acquired as a personal investment. A company was formed to hold and develop the lands, which was done in the succeeding years, and when their immense value had been fully proven, they were all turned over and distributed to the holders of Great Northern stock at cost. What the present and potential value of the lands is no one knows, but it is a safe judgment that they alone are worth more than the personal estate which Mr. Hill acquired during his lifetime.

During all the busy years he gave to the creation and building up of the great system of railway, not a cent of salary was ever drawn by him from it, he preferring to take his compensation in common with the stockholders, from the increased value of the properties. Unlike other transcontinental lines, the Great Northern received no land grant, or other aid from the Federal Government, excepting the grant originally made to the St. Paul and Pacific Company in Minnesota. Its securities were marketable because they had value behind them, and from the further fact that the interests of the road were in the hands of a man who always had made, and was believed to be always able to make, his word good.

In 1901, the Great Northern and the Northern Pacific Railways jointly purchased the stock of the Chicago, Burlington and Quincy Railroad Company, thus giving to his other lines access to the enormous producing and consuming territory of the upper Mississippi Valley, a territory which for extent and variety of wealth-producing area probably cannot be duplicated in the world.

Mr. Hill had planned to place all the properties, in which his stockholders and himself were interested, in a position to be secure from future speculative attacks, and to ensure the harmony which efficiency demands, by uniting them in the Northern Securities Company. That company was dissolved by the decision of a divided Court, but the management of the separate companies, so far, has remained successful and harmonious.

Although the chief activities of Mr. Hill's life were expended in the development of railways, he did work enough along other lines to have more than sufficed to keep an ordinary man fully occupied. The

keynote of such work was his desire to raise the average level of prosperity, of intelligence, and of public spirit. Undoubtedly, the greatest pleasure he took in his work was in the efforts he made and the success he achieved in improving agriculture and in increasing its profits. He led the farmer away from the one-crop idea, and taught him to diversify his industry by stock raising. He imported, at large personal expense, stock of the most profitable strains, and distributed it, after practical demonstration on his own large experimental farm, among the most intelligent farmers of the Northwest, most of whom he knew personally. This practice he continued through thirty years, and the splendid condition of the live stock interest of that section to-day is largely the result of his labors.

He taught soil restoration and rotation of crops; set up a laboratory for soil analysis, and established demonstration plots, on farms along the line of the railway, to demonstrate to the farmers, by object lessons, what startling results could be obtained by scientific fertilization and cultivation. He was always ready to talk to a group of farmers, and gave no small part of his life's forces, through his later years, to the effort to persuade them to better methods.

He was the first to advocate the conservation of natural resources on a large scale. The memorable address which he delivered in 1906 created a profound impression, and ran through many editions and languages. He made heavy demands on his business time and physical resources to comply with requests to address bodies of representative men assembled to discuss economic and scientific problems, but he regarded this as a form of public service which it was his duty to perform.

Irrigation, waterways, all forms of internal improvement, banking and other forms of finance, the theory of credit, and the virtue of thrift, every aspect of railroad operation, regulation, and improvement, almost every practical human activity received his study and profited by the conclusion of his wonderfully analytic and almost unerring mind. Some of the more important of these were grouped in his volume of economical and sociological discussions, entitled "Highways of Progress", published in 1910. It is amazing to observe, in that collection, the range of his thought, the wealth of his information, and the validity of his conclusions.

Among the larger interests of his later years was the acquisition of the two banks in St. Paul, and their consolidation under the name of the First National, to which was joined the Northwestern Trust Company, and all placed under the immediate control of one of his sons. This great financial institution is intended to be, not merely a clearing house for the enormous financial interests of the properties in which he was concerned, but an agency for liberating the Northwest from outside control, and for increasing and stabilizing its prosperity.

It has been and is a power in advancing the interests of the farmers and helping them to surer and larger returns. Until a few days before his death, he was as busy as he had been for years before, with plans for the upbuilding of the country and the improvement of the common lot.

He was a patron and lover of the arts. His collection of pictures is known at home and abroad by its excellence, and is the result of his judgment in selection. He was a connoisseur of precious stones, and his investments in these were marked by his usual good business judgment. He was an omnivorous reader, and, being possessed of a remarkable memory, had accumulated a wealth of detailed information upon a wide range of subjects, such as few men of his age, or any age or generation, ever possessed. His philanthropy did not stop with words, for he was extremely generous, in a practical, material way. He gave impartially to many educational institutions, his only condition being that the schools that received his aid should be conducted under the auspices of some religious denomination.

His private benefactions were constant and great; they were made with care and discrimination, and he avoided publicity in them to the last degree.

For many years, during the earlier part of his career, he cannot be said to have attracted, excepting among his own group of business associates and capitalists, the more than passing notice of the then leaders of thought and finance. He never attempted to attract such notice by spectacular staging of any of his enterprises. His sayings and doings were rather looked upon by most eastern men with a mild commiseration; but, as his system of railways developed, and the results of his so-called theories began to prove their value, and to be seen in many respects to be the very basic foundation of the prosperity of the railways of the country, they were copied by other systems, and, from train haul to accounting, the Great Northern was for years a school at which railway men were glad to learn; and many graduates from that school, trained by practical experience in its methods, can be found holding high positions in railway service, in all parts of the United States. During the last decade of his life, there was no one whose voice, in general economics and financial matters, was listened to with more respect than that of Mr. Hill. The judgment of no one man in this country, perhaps, counted for so much in determining American financiers to take up the first loan asked by the Allies. He thought its acceptance essential to our own business life and prosperity, and that his reasons were sound and his conclusions well taken, is amply proven by subsequent developments.

Though his plans were well wrought out, and the results he achieved came from thorough preparation, he could strike with lightning quickness and terrific force, whenever occasion demanded. He

was plain of speech, simple and sincere of thought, but a giant of power when roused to effort by obstacles that had to be overcome, and he was—first, last, and all the time—an American. The men on his railroads recognized his character and ability, and through all classes and ranks there ran a spirit of cheerful loyalty that could only have been evoked by a man of his wonderful personality. Among the many who were privileged to know him intimately, particularly the old-timers, who had been with him in the long-gone-by days of his early struggles, the feeling was one of deep and sincere affection, and everywhere, over the whole nation and in other countries, the general sentiment of respect and sorrow at his death, as a personal and public loss, has been deep and wide.

It is a safe prediction that the great record of what he achieved will insure increased recognition as time goes on. Yale University conferred upon him the degree of LL.D. in 1910. The Hill Professorship of Transportation was established at Harvard not long ago, with an endowment contributed by seventy-four friends who were delighted to do him this honor.

He was a man of quiet domestic tastes, and his serenest hours were those spent in his beautiful home at St. Paul, where his friends were always welcome, and from which they always came away feeling that they had been privileged to share in the happiness of an ideal American fireside. Throughout all his years, he demonstrated in his own life that a strict adherence to moral laws was a true attribute of greatness.

Much of the planning of his construction work in all lines was done in the seclusion of his home, to which he habitually drew men of all classes for conference and instructions, and his library there was the workshop in which was produced many of his masterpieces.

On August 19th, 1867, he was married to Miss Mary Theresa Mehegan, of St. Paul, and his widow, three sons, and six daughters survive him.

Volumes of anecdotes could be written to illustrate his manner of dealing with various situations. Through them all runs the strong vein of humor which was so marked a feature of his character. Above all, he asked for independence in judgment by his subordinates, and no surer path to his disfavor could be found than to endeavor to forestall his opinion, and recommend accordingly. Though he was a man of strong convictions, even in matters of minute detail, he was always open to argument, and ready to receive and weigh suggestions, and to give them consideration. Once a decision was made, however, he expected speed and economy in the prosecution of the project in hand, and was content with nothing less than the best results. Take him all in all, to one who understood in a measure the salient features of his individuality, and realized the broad view-point from which he regarded

every subject, he was an eminently satisfactory man to be associated with, and such association was a liberal education.

After Mr. Hill's death, hundreds of messages of sympathy poured in upon the family from all parts of the country, from lands across the sea, from people of the greatest diversity of condition. It was a spontaneous tribute which showed in what esteem he was held by high and low alike. Corporations, associations, municipal bodies, cities, and States, united to regret him and to do honor to his memory. It is impossible to reproduce here any considerable portion of these tributes; but an extract, as of date June 3d, 1916, from the minutes of the Board of Directors of the Great Northern Railway Company, the creation of which was his greatest life work, shows to what degree he was appreciated by his close associates:

"*Resolved*, That in the death of James J. Hill, the Great Northern Railway Company laments the loss of the man who brought it into being, who made it an instrument for the development of this country, who led it with unerring wisdom, who foresaw and safeguarded its future, and to whom it owes all that it has been and all it hopes to be."

James Jerome Hill was elected a Fellow of the American Society of Civil Engineers on January 10th, 1889.

VOL. LXXXI

SUBJECT INDEX

AGRICULTURE.

"A Complete Method for the Classification of Irrigable Lands." F. H. Peters. (With Discussion.) 222.

AMPHITHEATRE.

See **GRANDSTANDS AND STADIA.**

APPRAISAL.

See **VALUATION.**

BEAMS.

— of concrete and reinforced concrete. 1124 *et seq.*

BUILDINGS.

"Underpinning Trinity Vestry Building for Subway Construction." H. de B. Parsons. (With Discussion.) 74.

CABLEWAYS.

"An Aerial Tramway for the Saline Valley Salt Company, Inyo County, California." F. C. Carstarphen. 709. Discussion: Richard Lamb and H. F. Scholtz. 743.

CANALS.

— for irrigation; size, cost, etc. 237 *et seq.*

"Surges in an Open Canal." R. D. Johnson. (With Discussion.) 112.

"The Distribution of Stresses in Mitering Lock-Gates, with Special Reference to the Gates on the Panama Canal." Henry Goldmark. 1621.

CEMENT.

Analyses of — for test specimens of concrete to be immersed in sea water. 652.

Kinds of — defined. 1113.

CITIES.

Structural development of — . 585, 631.

COFFER-DAMS.

Coffer-dam used in raising the battleship *Maine;* also other sheet-piling — . 553.

"Unusual Coffer-Dam for 1 000-Foot Pier, New York City." Charles W. Staniford. 498. Discussion: Frederic R. Harris, D. A. Watt, C. A. Wentworth, Thomas H. Wiggin, T. Kennard Thomson, Charles S. Boardman, William M. Black, and F. E. Cudworth. 543.

COLÚMNS.

— of concrete and reinforced concrete. 1124 *et seq.*

CONCRETE.

— walls for 1 000-ft. pier. 532.

Disintegration of — . 682.

"Final Report of the Special Committee on — and Reinforced — ." (With Discussion.) 1101.

"Multiple-Arch Dams on Rush Creek, California." L. R. Jorgensen. (With Discussion.) 850.

"Tests of — Specimens in Sea Water, at Boston Navy Yard." R. E. Bakenhus. 645. Discussion: T. Kennard Thomson, J. J. Yates, J. R. McClintock, S. B. Williamson, Waldo C. Briggs, Charles S. Bilyeu, W. E. Day, Robert Ridgway, George W. Fuller, A. H. Rhett, Marshall W. Brown, Albert Larsen, W. Watters Pagon, R. J. Wig and Lewis R. Ferguson. 676.

Tests of — underpinning piles for subway on Fulton Street, New York City. 87 *et seq.*, 103 *et seq.*

CONTRACTOR'S PLANT.

— for constructing coffer-dam for 1 000-ft. pier. 528.

— , Lexington Avenue Subway, New York City. 379.

— , Stony River Dam. 1019.

COSTS OF WORK.

Cost data for excavating tunnels for Lexington Avenue Subway, New York City. 381.

Cost of constructing coffer-dam for New York City pier. 540.

Cost of constructing multiple-arch dams. 880.

— , Stony River Dam. 1022.

DAMS.

"Designing an Earth Dam Having a Gravel Foundation, with the Results Obtained in Tests on a Model." James B. Hays. 1. Discussion: W. G. Bligh, J. C. Oakes, C. E. Grunsky, H. T. Pease, Malcolm Elliott, Edward Wegmann, E. C. La Rue, George M. Bacon, H. A. Petterson, D. C. Henny, and Joseph Jacobs. 25.

Hydraulic-fill, diversion dam. 309, 335.

"Multiple-Arch — on Rush Creek, California." L. R. Jorgensen. 850. Discussion: F. O. Blackwell, A. D. Flinn, F. W. Scheidenhelm, Edward Wegmann, Walter J. Douglas, Edwin Duryea, L. H. Nishkian, Gardner S. Williams, and George W. Howson. 882.

"The Reconstruction of the Stony River Dam." F. W. Scheidenhelm. 907. Discussion: J. W. Ledoux, J. K. Finch, P. P. Rutenberg, Fred F. Moore, W. S. Downs, H. L. Coburn, H. F. Dunham,

Orrin L. Brodie, William Cain, Charles E. Gregory, Kenneth C. Grant, L. R. Jorgensen, Edward Wegmann, Irving P. Church, M. M. O'Shaughnessy, Joel D. Justin, and Ross M. Riegel. 1024.

DEPRECIATION.

See **VALUATION.**

DRAINAGE.

— for Yale Bowl. 264.

— of foundation soil, Stony River Dam. 988 *et seq.*

DRILLING.

Method of — used at Rogers Pass Tunnel. 464.

Methods and cost of — , Lexington Avenue Subway, New York City. 343.

EARTH PRESSURES.

" — : A Practical Comparison of Theories and Experiments." L. D. Cornish. 191. Discussion: William Cain, G. M. Braune, and F. N. Menefee. 202.

ECONOMICS.

"A Method of Determining a Reasonable Service Rate for Municipally Owned Public Utilities." J. B. Lippincott. (With Discussion.) 413.

"Final Report of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities." (With Discussion.) 1311.

"Final Report of the Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers. (With Discussion.) 1207.

EMBANKMENT.

Tests of model — . 506, 546, 548.

"The Yale Bowl." Charles A. Ferry. (With Discussion.) 249.

EMPLOYMENT.

"Final Report of the Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers." (With Discussion.) 1207.

ENGINEERING.

"Final Report of the Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers." (With Discussion.) 1207.

EXCAVATION.

Method of — in Rogers Pass Tunnel. 448.

Methods used in excavating tunnels for Lexington Avenue Subway, New York City. 341.

Rock — for 1 000-ft. pier. 528.

FILTRATION.

Comparison of well-water supply with filtered supply. 773.

FINANCE.

"A Method of Determining a Reasonable Service Rate for Municipally Owned Public Utilities." J. B. Lippincott. (With Discussion.) 413.

AUTHOR INDEX

AGNEW, AUGUSTUS WATEROUS.
Memoir of. 1792.

ALDEN, JOHN FERRIS.
Memoir of. 1674.

ALLISON, J. C.
"Control of the Colorado River as Related to the Protection of Imperial Valley." 297.

ANSON, WILLIAM FREDERICK ALFRED.
Memoir of. 1794.

APPLETON, THOMAS.
Memoir of. 1676.

ARNOLD, WILLIAM HARRY.
Memoir of. 1679.

ATWOOD, THOMAS C.
Yale Bowl. 280.

BABB, CYRUS C.
Floods and flood prevention. 1245.

BACON, GEORGE M.
Designing an earth dam. 47.

BAKENHUS, R. E.
"Tests of Concrete Specimens in Sea Water, at Boston Navy Yard." 645.

BARROWS, H. K.
Floods and flood prevention. 1282.

BENSEL, JOHN A.
"Final Report of the Special Committee on Floods and Flood Prevention." 1218.
"Final Report of the Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers." 1207.

BIGELOW, EDWARD MANNING.
Memoir of. 1681.

BILYEU, CHARLES S.
Tests of concrete in sea water. 684.

BINCKLEY, GEORGE S.
"Suggested Changes and Extension of the United States Weather Bureau Service in California: Report of a Committee of the Southern California Association of Members." 161.

BLACK, WILLIAM M.
Coffer-dam for 1 000-foot pier. 569.

BLACKWELL, F. O.
Multiple-arch dams. 882.

BLIGH, W. G.
Designing an earth dam. 25.

BOARDMAN, CHARLES S.
Coffer-dam for 1 000-foot pier. 553.

BOUCHER, WILLIAM J.
Valuation of land. 631.

BOWMAN, DANIEL WHEELER.
Memoir of. 1684.

BOYNTON, ROBERT HAMMOND.
Memoir of. 1796.

BRANNE, J. S.
Underpinning Trinity Vestry Building. 109.

BRAUNE, G. M.
Earth pressures. 216.

BRIGGS, WALDO C.
Tests of concrete in sea water. 683.

BRODIE, ORRIN L.
Reconstruction of Stony River Dam. 1041.

BROWN, MARSHALL W.
Tests of concrete in sea water. 692.

BUEL, A. W.
Underpinning Trinity Vestry Building. 109.

BURGESS, PHILIP.
Water supply of Parkersburg, W. Va. 811.

CAHN, ELIAS.
Underpinning Trinity Vestry Building. 103.

CAIN, WILLIAM.
Earth pressures. 202.
Reconstruction of Stony River Dam. 1044.

CALDWELL, CHARLES ADOLPHUS.
Memoir of. 1687.

CANFIELD, EDWARD.
Memoir of. 1689.

CARPENTER, J. C.
"The Properties of Balsa Wood (*Ochroma Lagopus*)." 125.

CARSTARPHEN, F. C.
"An Aerial Tramway for the Saline Valley Salt Company, Inyo County, California." 709.

CHITTENDEN, H. M.
Floods and flood prevention. 1256.

CHURCH, IRVING P.
Reconstruction of Stony River Dam. 1076.
Surges in an open canal. 119.

CHURCHILL, CHARLES S.
"Final Report of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities." 1311.

CLARK, H. F.
Municipally owned public utilities. 432.

COBURN, H. L.
Reconstruction of Stony River Dam. 1038.

COHEN, MENDES.
Memoir of. 1656.

CONNELLY, JOSEPH A. A.
Underpinning Trinity Vestry Building. 108.

CORNISH, L. D.
"Earth Pressures: A Practical Comparison of Theories and Experiments." 191.

CORTHELL, ELMER LAWRENCE.
Memoir of. 1658.

COX, LEONARD M.
Properties of balsa wood. 160.

CUDWORTH, F. E.
Coffer-dam for 1 000-foot pier. 569.

CUNNINGHAM, ANDREW CHASE.
Memoir of. 1691.

CUNNINGHAM, DAVID WEST.
Memoir of. 1695.

CUNTZ, WILLIAM COOPER.
Memoir of. 1825.

DABNEY, T. G.
"Final Report of the Special Committee on Floods and Flood Prevention." 1218.

DAVIES, J. V.
Tunnel construction methods. 483.

DAY, W. E.
Tests of concrete in sea water. 684.

DENNIS, A. C.
"Construction Methods for Rogers Pass Tunnel." 448.

DEYO, S. L. F.
"Final Report of the Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers." 1207.

DONALDSON, FRANCIS.
Subway tunnel work. 405.

DOUGHERTY, R. E.
Tunnel construction methods. 486.

DOUGLAS, WALTER J.
Multiple-arch dams. 892.

DOWNS, W. S.
Reconstruction of Stony River Dam. 1036.

DRURY, EDMUND HAZEN.
Memoir of. 1697.

Du BOIS, AUGUSTUS JAY.
Memoir of. 1699.

DUNHAM, H. F.
Reconstruction of Stony River Dam. 1039.
Water supply of Parkersburg, W. Va. 806.
Yale Bowl. 286.

DURYEA, EDWIN.
Multiple-arch dams. 894.

EAKIN, H. M.
Floods and flood prevention. 1235.

EDDY, HENRY T.
Concrete and reinforced concrete. 1167.

ELLIOTT, MALCOLM.
Designing an earth dam. 39.

ELLIS, JOHN WALDO.
Memoir of. 1702.

ELY, THEODORE NEWEL.
Memoir of. 1705.

ENGSTRÖM, FRANS.
Memoir of. 1798.

EVANS, RICHARD.
Memoir of. 1709.

FERGUSON, LEWIS R.
Tests of concrete in sea water. 703.

FERRY, CHARLES A.
"The Yale Bowl." 249.

FINCH, J. K.
Reconstruction of Stony River Dam. 1027.

FIRMSTONE, FRANK.
Memoir of. 1711.

FLINN, A. D.
Multiple-arch dams. 884.

FOUHY, JAMES F.
Underpinning Trinity Vestry Building. 107.

FRENCH, J. B.
Yale Bowl. 283.

FROST, GEORGE HENRY.
Memoir of. 1827.

FUERTES, JAMES H.
Water supply of Parkersburg, W. Va. 821.

FULLER, GEORGE W.
Tests of concrete in sea water. 685.
Water supply of Parkersburg, W. Va. 796.

FULLER, MYRON L.
Floods and flood prevention. 1269.

GANNETT, FARLEY.
Floods and flood prevention. 1288.

GAYLER, CARL.
Concrete and reinforced concrete. 1163.

GOLDMARK, HENRY.
"The Distribution of Stresses in Mitering Lock-Gates, with Special Reference to the Gates on the Panama Canal." 1621.

GRANT, KENNETH C.
Floods and flood prevention. 1245.
Reconstruction of Stony River Dam. 1066.

GREENE, HOWARD ARNOLD.
Memoir of. 1800.

GREGORY, CHARLES E.
Reconstruction of Stony River Dam. 1058.

GREINER, J. E.
"Final Report of the Special Committee on Concrete and Reinforced Concrete." 1101.

GRIEST, MAURICE.
Subway tunnel work. 392.

GRIMSHAW, JAMES WALTER.
Memoir of. 1712.

GROAT, B. F.
Floods and flood prevention. 1255.

GROVER, N. C.
Floods and flood prevention. 1283.
Weather Bureau service in California. 171.

GRUNSKY, C. E.
Designing an earth dam. 33.
"Final Report of the Special Committee on Floods and Flood Prevention." 1218, 1295.
Valuation of public utilities. 1590.

HALL, WILLIAM M.
"The Water Supply of Parkersburg, W. Va." 749.

HARRIS, FRANK S. M.
Municipally owned public utilities. 423.

HARRIS, FREDERIC R.
Coffer-dam for 1 000-foot pier. 543.

HARTE, CHARLES RUFUS.
Underpinning Trinity Vestry Building. 107.

HATT, W. K.
"Final Report of the Special Committee on Concrete and Reinforced Concrete." 1101.

HAYS, JAMES B.
"Designing an Earth Dam Having a Gravel Foundation, with the Results Obtained in Tests on a Model." 1.

HAZEN, ALLEN.
Municipally owned public utilities. 435.

HENDERER, WILLIAM OSWALD.
Memoir of. 1713.

HENNY, D. C.
Designing an earth dam. 55.

HIDER, ARTHUR.
Memoir of. 1715.

HILL, JAMES JEROME.
Memoir of. 1829.

HILL, JOHN W.
Floods and flood prevention. 1236.
Water supply of Parkersburg, W. Va. 788.

HILL, NICHOLAS S., JR.
Water supply of Parkersburg, W. Va. 801.

HINCKLEY, H. V.
Concrete and reinforced concrete. 1166.

HITT, HENRY C.
Yale Bowl. 286.

HOAG, SIDNEY WILLETT, JR.
Memoir of. 1718.

HOFF, OLAF.
"Final Report of the Special Committee on Concrete and Reinforced Concrete." 1101.

HOTCHKISS, CHARLES WILCOX.
Memoir of. 1721.

HOUSTON, G. N.
Classification of irrigable lands. 244.

HOWSON, GEORGE W.
Multiple-arch dams. 900.

HULSART, C. R.
Tunnel construction methods. 487.

HUMPHREY, RICHARD L.
"Final Report of the Special Committee on Concrete and Reinforced Concrete." 1101.

HUNTER, WILLIAM HENRY.
Memoir of. 1723.

HYDE, WILLIAM HERBERT.
Memoir of. 1802.

IRVING, W. G.
Municipally owned public utilities. 437.

JACKSON, DUGALD C.
"Final Report of the Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers." 1207.

JACOBS, JOSEPH.
Designing an earth dam. 59.

JACOBS, ROBERT H.
Subway tunnel work. 397.

JENKINS, JAMES EDGAR.
Memoir of. 1725.

JERRARD, L. P.
"The Valuation of Land." 582.

JOHNSON, R. D.
"Surges in an Open Canal." 112.

JOHNSON, THEODORE S.
Water supply of Parkersburg, W. Va. 807.

JONES, LEWIS A.
Compensation of civil engineers. 1216.

JORDAN, LEONARD C.
Municipally owned public utilities. 428.

JORGENSEN, L. R.
"Multiple-Arch Dams on Rush Creek, California." 850.
Reconstruction of Stony River Dam. 1070.

JUDSON, WILLIAM V.
"Final Report of the Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers." 1207.

JUSTIN, JOEL D.
Reconstruction of Stony River Dam. 1082.

KATIGBAK, JOSÉ PETRONIO.
Memoir of. 1803.

KATTÉ, WALTER.
Memoir of. 1727.

KEAYS, R. H.
Tunnel construction methods. 474.

KEITH, H. C.
Yale Bowl. 285.

KELLY, HUGH A.
Valuation of land. 619.

KENNISON, KARL R.
Surges in an open canal. 116.

KING, W. I.
Valuation of land. 618.

KING, WILLIAM BYRD.
Memoir of. 1733.

KNOWLES, MORRIS.
"Final Report of the Special Committee on Floods and Flood Prevention." 1230.
Water supply of Parkersburg, W. Va. 832.

KNOWLES, S. A.
Tunnel construction methods. 485.

LAMB, RICHARD.
Aerial tramway. 743.

LARSEN, ALBERT.
Tests of concrete in sea water. 693.

LA RUE, E. C.
Designing an earth dam. 43.
Floods and flood prevention. 1286.

LAUCHLI, E.
Tunnel construction methods. 471.

LAVIS, F.

Tunnel construction methods. 476.

LEDOUX, J. W.

Reconstruction of Stony River Dam. 1024.

LEE, CHARLES H.

"Suggested Changes and Extension of the United States Weather Bureau Service in California: Report of a Committee of the Southern California Association of Members." 161.

LEEDS, CHARLES T.

Weather Bureau service in California. 173.

LEIGHTON, M. O.

Floods and flood prevention. 1241.

LESLEY, ROBERT W.

"Final Report of the Special Committee on Concrete and Reinforced Concrete." 1101.

LEWIS, EUGENE CASTNER.

Memoir of. 1735.

LEWIS, NELSON P.

"Final Report of the Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers. 1207.

LIPPINCOTT, J. B.

"A Method of Determining a Reasonable Service Rate for Municipally Owned Public Utilities." 413.

"Final Report of the Special Committee on Floods and Flood Prevention." 1218.

Weather Bureau service in California. 181.

LOWETH, C. F.

"Final Report of the Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers." 1207.

LUNDIN, A. P.

Properties of balsa wood. 156.

LYNCH, ALEXANDER S.

Yale Bowl. 290.

MacCALLUM, ALEXANDER WILLIAM.

Memoir of. 1741.

MacCRACKEN, GEORGE GERE.

Memoir of. 1806.

McCANN, W. R.
Valuation of public utilities. 1610.

McCLINTOCK, J. R.
Tests of concrete in sea water. 682.

McCOOL, DANIEL.
Memoir of. 1744.

McKENZIE, THEODORE HALL.
Memoir of. 1746.

McMULLEN, STANLEY HASTINGS.
Memoir of. 1808.

MADDEN, JOHN H.
Subway tunnel work. 393.

MATTHES, GERARD H.
Floods and flood prevention. 1278.

MAYER, JOSEPH.
Valuation of public utilities. 1597.

MAYO, FRANKLIN F.
Valuation of land. 638.

MEAD, DANIEL W.
"Final Report of the Special Committee on Floods and Flood Prevention." 1218.

MEEM, JAMES C.
Underpinning Trinity Vestry Building. 162.

MENEFEE, F. N.
Earth pressures. 218.

METCALF, LEONARD.
"Final Report of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities." 1311.

MILLER, STANLEY ALFRED.
Memoir of. 1749.

MOORE, FRED F.
Reconstruction of Stony River Dam. 1035.

MOULTON, H. G.
Subway tunnel work. 400.

MYERS, JOHN H.
Subway tunnel work. 399.

NEELY, WILLIAM RIDLEY.
Memoir of. 1752.

NISHKIAN, L. H.
Multiple-arch dams. 898.

OAKES, J. C.
Designing an earth dam. 28.

OCKERSON, J. A.
Control of the Colorado River. 333.
"Final Report of the Special Committee on Floods and Flood Prevention." 1218.

O'SHAUGHNESSY, M. M.
Reconstruction of Stony River Dam. 1081.

PAGON, W. WATTERS.
Tests of concrete in sea water. 699.

PARKER, HAROLD.
Memoir of. 1755.

PARSONS, H. de B.
"Underpinning Trinity Vestry Building for Subway Construction." 74.

PARTHESIUS, PHILIP HENRY.
Memoir of. 1810.

PATTERSON, WILLIAM RODNEY.
Memoir of. 1757.

PEASE, H. T.
Designing an earth dam. 37.

PETERS, F. H.
"A Complete Method for the Classification of Irrigable Lands." 222.

PETTERSON, H. A.
Designing an earth dam. 47.

PICKETT, WILLIAM DOUGLAS.
Memoir of. 1671.

POMEROY, LEWIS ROBERTS.
Memoir of. 1811.

POST, WILLIAM S.
Weather Bureau service in California. 172.

POTTER, ALEXANDER.
Water supply of Parkersburg, W. Va. 792.

POWERS, C. V. V.
Subway tunnel work. 405.

RAMSEY, JOSEPH, JR.
Memoir of. 1759.

RANKIN, EDWARD S.
Valuation of land. 626.

RAYMOND, WILLIAM G.
"Final Report of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities." 1311.

RHETT, A. H.
Concrete and reinforced concrete. 1153.
Tests of concrete in sea water. 688.

RICHARDSON, THOMAS FRANKLIN.
Memoir of. 1761.

RIDGWAY, ROBERT.
Subway tunnel work. 404.
Tests of concrete in sea water. 684.

RIEGEL, ROSS M.
Reconstruction of Stony River Dam. 1086.

RIGGS, HENRY E.
"Final Report of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities." 1311.

ROY, ROBERT MAITLAND.
Memoir of. 1765.

RUNDLETT, LEONARD WARREN.
Memoir of. 1766.

RUTENBERG, P. P.
Reconstruction of Stony River Dam. 1029.

SAFFORD, ARTHUR T.
"Final Report of the Special Committee on Floods and Flood Prevention." 1218.

SANBORN, JAMES F.
Tunnel construction methods. 478.

SAVILLE, CHARLES.
"Final Report of the Special Committee on Floods and Flood Prevention." 1218.

SCHEIDENHELM, F. W.
Multiple-arch dams. 885.
"The Reconstruction of the Stony River Dam." 907.

SCHICK, H. S.
Compensation of civil engineers. 1216.

SCHNEIDER, CHARLES CONRAD.
Memoir of. 1665.

SCHOLTZ, H. F.
Aerial tramway. 745.

SCOTT, WILLIAM FRY.
Concrete and reinforced concrete. 1159.

SELLEW, F. L.
"Final Report of the Special Committee on Floods and Flood Prevention." 1218.

SHAILER, ROBERT A.
Tunnel construction methods. 473.

SHAW, WILLIAM THOMAS.
Memoir of. 1813.

SHEDD, FRANK EDSON.
Memoir of. 1768.

SIMSON, DAVID.
Memoir of. 1770.

SINCLAIR, FRANK OSCAR.
Memoir of. 1772.

SMITH, WILLIAM STUART.
Memoir of. 1815.

SNOW, JONATHAN P.
"Final Report of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities." 1311.

SONDEREGGER, A. L.
Control of the Colorado River. 326.

SPEAR, WALTER E.
Water supply of Parkersburg, W. Va. 804.

SPENCE, DAVID WENDEL.
Memoir of. 1774.

STANIFORD, CHARLES W.
"Unusual Coffer-Dam for 1 000-Foot Pier, New York City." 498.

STEARNS, FREDERIC P.
"Final Report of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities." 1311.

STEVENSON, J. D.
Water supply of Parkersburg, W. Va. 832.

STOTT, HENRY GORDON.
Memoir of. 1776.

STUART, FRANCIS LEE.
Tunnel construction methods. 481.

SULLIVAN, J. G.
Tunnel construction methods. 489.

SWENSSON, EMIL.
"Final Report of the Special Committee on Concrete and Reinforced Concrete." 1101.

TALBOT, ARTHUR N.
"Final Report of the Special Committee on Concrete and Reinforced Concrete." 1101.

TATUM, SLEDGE.
Memoir of. 1779.

TERRY, EDWARD CLINTON.
Memoir of. 1781.

THOMSON, SAMUEL FORSYTHE.
Memoir of. 1817.

THOMSON, T. KENNARD.
Classification of irrigable lands. 243.
Coffer-dam for 1 000-foot pier. 551.
Municipally owned public utilities. 424.
Subway tunnel work. 398.
Tests of concrete in sea water. 676.
Tunnel construction methods. 479.
Underpinning Trinity Vestry Building. 104.
Valuation of land. 628.
Water supply of Parkersburg, W. Va. 805.

TIBBETTS, FRED. H.
Weather Bureau service in California. 177.

TILLSON, GEORGE W.
"Final Report of the Special Committee to Investigate the Conditions of Employment of, and Compensation of, Civil Engineers." 1207.

TOLMAN, EDWARD MAYO.
Water supply of Parkersburg, W. Va. 838.

TOWNSEND, C. McD.
"Final Report of the Special Committee on Floods and Flood Prevention." 1218.

TURNEAURE, F. E.
Concrete and reinforced concrete. 1199.

TURNER, C. A. P.
Concrete and reinforced concrete. 1193.

VANSITTART, GEORGE EDWARD.
Memoir of. 1821.

VEUVE, ERLE LEROY.
Memoir of. 1784.

VOORHEES, THEODORE.
Memoir of. 1786.

WALKER, J. S.
Valuation of land. 629.

WARNER, JAMES MADISON.
Memoir of. 1823.

WATT, D. A.
Coffer-dam for 1 000-foot pier. 544.

WEGMANN, EDWARD.
Designing an earth dam. 42.
Multiple-arch dams. 890.
Reconstruction of Stony River Dam. 1071.

WENTWORTH, C. A.
Coffer-dam for 1 000-foot pier. 545.

WERBIN, ISRAEL V.
"Tunnel Work on Sections 8, 9, 10, and 11, Broadway-Lexington Avenue Subway, New York City." 341.

WESTON, EDMUND BROWNELL.
Memoir of. 1789.

WHITE, LAZARUS.
Tunnel construction methods. 478.

WHITNEY, H. A.

Municipally owned public utilities. 438.

WIG, R. J.

Tests of concrete in sea water. 703.

WIGGIN, THOMAS H.

Coffer-dam for 1 000-foot pier. 548.
